Simple to take.

ROCHE

in acute otitis media

- Penetrates and clears middle-ear fluid of susceptible strains of *H. influenzae* and *S. pneumoniae*[1]
- Reduces evidence of inflammation and bulging eardrum[2]
- Results in a reduction of fever, pain and other symptoms[2,3]

Active against 86% of *H. influenzae in vitro*—even amoxicillin- and ampicillin-resistant strains

Overall, 86% of *Haemophilus influenzae* strains taken from sputum cultures prove susceptible *in vitro* to Bactrim.[4] In one study, 100% of 191 ampicillin-resistant *H. influenzae* isolates were susceptible to Bactrim.[5] However, *in vitro* data do not necessarily correlate with clinical results.

Active against 91% of *S. pneumoniae in vitro*

In sputum cultures of *Streptococcus pneumoniae,* the most frequent pathogen in acute otitis media, 91% of isolates show susceptibility *in vitro* to Bactrim.[4]

Excellent clinical activity—and economical

In comparative clinical trials in children with acute otitis media, Bactrim *b.i.d.* was unsurpassed by ampicillin, amoxicillin or cefaclor.[6]
And the average cost of Bactrim is lower than that of cefaclor and comparable to that of ampicillin and amoxicillin.[7]
Bactrim is indicated in acute otitis media due to susceptible organisms when it offers an advantage over other antimicrobials. Bactrim is contraindicated in pregnancy, lactation, infants under two months of age and documented megaloblastic anemia due to folate deficiency. To date, there are limited data on the safety of repeated use of Bactrim in children under two years of age.

Cherry-flavored suspension

Bactrim™ Pediatric

(trimethoprim and sulfamethoxazole/Roche)

B.I.D. for enhanced compliance.

BACTRIM™ (trimethoprim and sulfamethoxazole/Roche)

Before prescribing, please consult complete product information, a summary of which follows:

Indications and Usage: For the treatment of urinary tract infections due to susceptible strains of the following organisms: *Escherichia coli, Klebsiella-Enterobacter, Proteus mirabilis, Proteus vulgaris, Proteus morganii*. It is recommended that initial episodes of uncomplicated urinary tract infections be treated with a single effective antibacterial agent rather than the combination. *Note:* The increasing frequency of resistant organisms limits the usefulness of all antibacterials, especially in these urinary tract infections.

For acute otitis media in children due to susceptible strains of *Haemophilus influenzae* or *Streptococcus pneumoniae* when in physician's judgment it offers an advantage over other antimicrobials. To date, there are limited data on the safety of repeated use of Bactrim in children under two years of age. Bactrim is not indicated for prophylactic or prolonged administration in otitis media at any age.

For acute exacerbations of chronic bronchitis in adults due to susceptible strains of *Haemophilus influenzae* or *Streptococcus pneumoniae* when in physician's judgment it offers an advantage over a single antimicrobial agent.

For enteritis due to susceptible strains of *Shigella flexneri* and *Shigella sonnei* when antibacterial therapy is indicated.

Also for the treatment of documented *Pneumocystis carinii* pneumonitis.

Contraindications: Hypersensitivity to trimethoprim or sulfonamides; patients with documented megaloblastic anemia due to folate deficiency; pregnancy at term; nursing mothers because sulfonamides are excreted in human milk and may cause kernicterus; infants less than 2 months of age.

Warnings: BACTRIM SHOULD NOT BE USED TO TREAT STREPTOCOCCAL PHARYNGITIS. Clinical studies show that patients with group A β-hemolytic streptococcal tonsillopharyngitis have higher incidence of bacteriologic failure when treated with Bactrim than do those treated with penicillin. Deaths from hypersensitivity reactions, hepatocellular necrosis, agranulocytosis, aplastic anemia and other blood dyscrasias have been associated with sulfonamides. Experience with trimethoprim is much more limited but occasional interference with hematopoiesis has been reported as well as an increased incidence of thrombopenia with purpura in elderly patients on certain diuretics, primarily thiazides. Sore throat, fever, pallor, purpura or jaundice may be early signs of serious blood disorders. Frequent CBC's are recommended; therapy should be discontinued if a significantly reduced count of any formed blood element is noted.

Precautions: *General:* Use cautiously in patients with impaired renal or hepatic function, possible folate deficiency, severe allergy or bronchial asthma. In patients with glucose-6-phosphate dehydrogenase deficiency, hemolysis, frequently dose-related, may occur. During therapy, maintain adequate fluid intake and perform frequent urinalyses, with careful microscopic examination, and renal function tests, particularly where there is impaired renal function. Bactrim may prolong prothrombin time in those receiving warfarin; reassess coagulation time when administering Bactrim to these patients.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Because trimethoprim and sulfamethoxazole may interfere with folic acid metabolism, use during pregnancy only if potential benefits justify the potential risk to the fetus.

Adverse Reactions: All major reactions to sulfonamides and trimethoprim are included, even if not reported with Bactrim. *Blood dyscrasias:* Agranulocytosis, aplastic anemia, megaloblastic anemia, thrombopenia, leukopenia, hemolytic anemia, purpura, hypoprothrombinemia and methemoglobinemia. *Allergic reactions:* Erythema multiforme, Stevens-Johnson syndrome, generalized skin eruptions, epidermal necrolysis, urticaria, serum sickness, pruritus, exfoliative dermatitis, anaphylactoid reactions, periorbital edema, conjunctival and scleral injection, photosensitization, arthralgia and allergic myocarditis. *Gastrointestinal reactions:* Glossitis, stomatitis, nausea, emesis, abdominal pains, hepatitis, hepatocellular necrosis, diarrhea, pseudomembranous colitis and pancreatitis. *CNS reactions:* Headache, peripheral neuritis, mental depression, convulsions, ataxia, hallucinations, tinnitus, vertigo, insomnia, apathy, fatigue, muscle weakness and nervousness. *Miscellaneous reactions:* Drug fever, chills, toxic nephrosis with oliguria and anuria, periarteritis nodosa and L.E. phenomenon. Due to certain chemical similarities to some goitrogens, diuretics (acetazolamide, thiazides) and oral hypoglycemic agents, sulfonamides have caused rare instances of goiter production, diuresis and hypoglycemia in patients; cross-sensitivity with these agents may exist. In rats, long-term therapy with sulfonamides has produced thyroid malignancies.

Dosage: Not recommended for infants less than two months of age.

URINARY TRACT INFECTIONS AND SHIGELLOSIS IN ADULTS AND CHILDREN, AND ACUTE OTITIS MEDIA IN CHILDREN:

Adults: Usual adult dosage for urinary tract infections—1 DS tablet (double strength), 2 tablets (single strength) or 4 teasp. (20 ml) b.i.d. for 10-14 days. Use identical daily dosage for 5 days for shigellosis.

Children: Recommended dosage for children with urinary tract infections or acute otitis media—8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole per 24 hours, in two divided doses for 10 days. Use identical daily dosage for 5 days for shigellosis.

For patients with renal impairment: Use recommended dosage regimen when creatinine clearance is above 30 ml/min. If creatinine clearance is between 15 and 30 ml/min, use one-half the usual regimen. Bactrim is not recommended if creatinine clearance is below 15 ml/min.

ACUTE EXACERBATIONS OF CHRONIC BRONCHITIS IN ADULTS:

Usual adult dosage: 1 DS tablet (double strength), 2 tablets (single strength) or 4 teasp. (20 ml) b.i.d. for 14 days.

PNEUMOCYSTIS CARINII PNEUMONITIS:

Recommended dosage: 20 mg/kg trimethoprim and 100 mg/kg sulfamethoxazole per 24 hours in equal doses every 6 hours for 14 days. See complete product information for suggested children's dosage table.

Supplied: *Double Strength (DS) tablets,* each containing 160 mg trimethoprim and 800 mg sulfamethoxazole, bottles of 100, 250 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 20. *Tablets,* each containing 80 mg trimethoprim and 400 mg sulfamethoxazole—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 40. *Pediatric Suspension,* containing 40 mg trimethoprim and 200 mg sulfamethoxazole per teaspoonful (5 ml); cherry flavored—bottles of 100 ml and 16 oz (1 pint). *Suspension,* containing 40 mg trimethoprim and 200 mg sulfamethoxazole per teaspoonful (5 ml); fruit-licorice flavored—bottles of 16 oz (1 pint).

PRESENTS

WILDERNESS MEDICINE
August 12-16, 1985
Lake Tahoe, Nevada

This CME course (23 credit hours in Category I, ACEP, AAFP) has been developed for physicians and other health care professionals who love the outdoors - the open spaces. It will provide the knowledge and skills needed to manage medical problems encountered away from the office, hospital and clinical laboratory.

United Airlines will be offering special airfares, not available to the general public. The meeting will be held at the **Hyatt Lake Tahoe** in Incline Village. A social program has been designed to complement the educational experience.

The fee is $295.

WEST: Media Services—Lynne Jeffes, Darien DeLorenzo, 1340 Paloma Avenue, Burlingame, CA 94010 • (415) 348-7478/550-0519

CLASSIFIED: 44 Gough Street, San Francisco, CA 94103-1233 • Tel: (415) 863-5522/863-6853

Advertisements—The journal is published the first week of the month. Advertising copy must be received no later than the first of the month preceding issue. Advertising rates will be sent on request. Acceptance of advertising is contingent upon approval by the Advertising Committee. *The journal reserves the right to reject any advertisement.*

SUBSCRIPTION INFORMATION

The subscription price per year is $20 in the United States and Canada (US funds); $30 in all other countries. Single copies are $4.50 (which includes postage and handling). Address all subscription communications to THE WESTERN JOURNAL OF MEDICINE Circulation, 44 Gough Street, San Francisco, CA 94103-1233 • Tel: (415) 863-5522

Allow six weeks for subscriptions to begin. Past issues must be bought individually. So long as reserve stocks are available, missing issue requests from subscribers are honored for up to six months after the issue date. Thereafter, the single copy rate of $4.50 is applicable for each issue available.

Change of Address—Requests for change of address should give both the old and new address. Allow six weeks for changeover.

SUBMITTING MANUSCRIPTS

"Information for Authors"—A complete guide to manuscript submission and journal style is available on request and also appears in January and July.

Author Responsibility—Authors are responsible for all statements, conclusions and methods of presenting subjects. Articles are accepted on condition that they are contributed solely to this journal.

Manuscripts—Ordinarily manuscripts should not exceed 3,000 words (less than 15 typed double-spaced pages). The original manuscript and two copies should be submitted, typed double-spaced throughout. If photographic illustrations are desired, three sets of clear, unmounted black and white glossy prints should be supplied. For line drawings, original artwork or glossy prints are acceptable. Tables should be typed on separate sheets of paper.

Clinical Investigation—Papers that authors wish considered for the Clinical Investigation section should be so designated in the transmittal letter.

SORBITRATE™
(ISOSORBIDE DINITRATE)

Please consult full prescribing information before use. A summary follows:

INDICATIONS AND USAGE: SORBITRATE (isosorbide dinitrate) is indicated for the treatment and prevention of angina pectoris. All dosage forms of isosorbide dinitrate may be used prophylactically to decrease frequency and severity of anginal attacks and can be expected to decrease the need for sublingual nitroglycerin.

The sublingual and chewable forms of the drug are indicated for acute prophylaxis of angina pectoris when taken a few minutes before situations likely to provoke anginal attacks. Because of a slower onset of effect, the oral forms of isosorbide dinitrate are not indicated for acute prophylaxis.

CONTRAINDICATIONS: SORBITRATE is contraindicated in patients who have shown purported hypersensitivity or idiosyncrasy to it or other nitrates or nitrites. Epinephrine and related compounds are ineffective in reversing the severe hypotensive events associated with overdose and are contraindicated in this situation.

WARNINGS: The benefits of SORBITRATE during the early days of an acute myocardial infarction have not been established. If one elects to use organic nitrates in early infarction, hemodynamic monitoring and frequent clinical assessment should be used because of the potential deleterious effects of hypotension.

PRECAUTIONS: General: Severe hypotensive response, particularly with upright posture, may occur with even small doses of SORBITRATE. The drug should therefore be used with caution in subjects who may have blood volume depletion from diuretic therapy or in subjects who have low systolic blood pressure (eg, below 90 mmHg). Paradoxical bradycardia and increased angina pectoris may accompany nitrate-induced hypotension. Nitrate therapy may aggravate the angina caused by hypertrophic cardiomyopathy.

Marked symptomatic, orthostatic hypotension has been reported when calcium channel blockers and organic nitrates were used in combination. Dose adjustment of either class of agents may be necessary.

Tolerance to this drug and cross-tolerance to other nitrates and nitrites may occur. Tolerance to the vascular and antianginal effects of isosorbide dinitrate or nitroglycerin has been demonstrated in clinical trials, experience through occupational exposure, and in isolated tissue experiments in the laboratory. The importance of tolerance to the appropriate use of isosorbide dinitrate in the management of patients with angina pectoris has not been determined. However, one clinical trial using treadmill exercise tolerance (as an end point) found an 8-hour duration of action of oral isosorbide dinitrate following the first dose (after a 2-week placebo washout) and only a 2-hour duration of effect of the same dose after 1 week of repetitive dosing at conventional dosing intervals. On the other hand, several trials have been able to differentiate isosorbide dinitrate from placebo after 4 weeks of therapy and, in open trials, an effect seems detectable for as long as several months.

Tolerance clearly occurs in industrial workers continuously exposed to nitroglycerin. Moreover, physical dependence also occurs since chest pain, acute myocardial infarction, and even sudden death have occurred during temporary withdrawal of nitroglycerin from the workers. In clinical trials in angina patients, there are reports of anginal attacks being more easily provoked and of rebound in the hemodynamic effects soon after nitrate withdrawal. The relative importance of these observations to the routine, clinical use of isosorbide dinitrate is not known. However, it seems prudent to gradually withdraw patients from isosorbide dinitrate when the therapy is being terminated, rather than stopping the drug abruptly.

Information for Patients: Headache may occur during initial therapy with SORBITRATE. Headache is usually relieved by the use of standard headache remedies or by lowering the dose and tends to disappear after the first week or two of use.

Drug Interactions: Alcohol may enhance any marked sensitivity to the hypotensive effect of nitrates.

Isosorbide dinitrate acts directly on vascular smooth muscle, therefore, any other agent that depends on vascular smooth muscle as the final common path can be expected to have decreased or increased effect depending on the agent.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No long-term studies in animals have been performed to evaluate the carcinogenic potential of this drug. A modified two-litter reproduction study in rats fed isosorbide dinitrate at 25 or 100 mg/kg/day did not reveal any effects on fertility or gestation or any remarkable gross pathology in any parent or offspring fed isosorbide dinitrate as compared with rats fed a basal-controlled diet.

Pregnancy Category C: Isosorbide dinitrate has been shown to cause a dose-related increase in embryotoxicity (increase in mummified pups) in rabbits at oral doses 35 and 150 times the maximum recommended human daily dose. There are no adequate and well-controlled studies in pregnant women. SORBITRATE should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when SORBITRATE is administered to a nursing woman.

Pediatric Use: The safety and effectiveness of SORBITRATE in children has not been established.

ADVERSE REACTIONS: Adverse reactions, particularly headache and hypotension, are dose-related. In clinical trials at various doses, the following have been observed.

Headache is the most common (reported incidence varies widely, apparently being dose-related, with an average occurrence of about 25%) adverse reaction and may be severe and persistent. Cutaneous vasodilation with flushing may occur. Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop (the incidence of reported symptomatic hypotension ranges from 2% to 36%). An occasional individual will exhibit marked sensitivity to the hypotensive effects of nitrates and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration, and collapse) may occur even with the usual therapeutic dose. Drug rash and/or exfoliative dermatitis may occasionally occur. Nausea and vomiting appear to be uncommon. Case reports of clinically significant methemoglobinemia are rare at conventional doses of organic nitrates. The formation of methemoglobin is dose-related and, in the case of genetic abnormalities of hemoglobin that favor methemoglobin formation, even conventional doses of organic nitrate could produce harmful concentrations of methemoglobin.

DOSAGE AND ADMINISTRATION: For the treatment of angina pectoris, the usual starting dose for sublingual SORBITRATE is 2.5 to 5 mg; for chewable tablets, 5 mg; for oral (swallowed) tablets, 5 to 20 mg, and for controlled release forms, 40 mg.

SORBITRATE should be titrated upward until angina is relieved or side effects limit the dose. In ambulatory patients, the magnitude of the incremental dose increase should be guided by measurements of standing blood pressure.

The initial dosage of sublingual or chewable SORBITRATE for prophylactic therapy in angina pectoris patients is generally 5 or 10 mg every 2 to 3 hours. Adequate controlled clinical studies demonstrating the effectiveness of chronic maintenance therapy with these dosage forms have not been reported.

SORBITRATE in oral doses of 10 to 40 mg given every 6 hours or in oral controlled-release doses of 40 to 80 mg given every 8 to 12 hours is generally recommended. The extent to which development of tolerance should modify the dosage program has not been defined. *The oral controlled-release forms of isosorbide dinitrate should not be chewed.*

DOSAGE FORMS AVAILABLE: Sublingual Tablets (2.5, 5, 10 mg), Chewable Tablets (5, 10 mg), Oral Tablets (5, 10, 20, 30, 40 mg); Sustained Action Tablets (40 mg).

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure – Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal – Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) – PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of β_2 receptors.

Major Surgery – Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia – Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis – Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: impaired Renal Function – Use nadolol with caution (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients – Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign of impending failure. Advise patients in event of missed doses.

Drug interactions – Concurrent administration may result in interactions with: Anesthetics, general – exaggeration of the hypotension induced by general anesthetics (see WARNINGS, Major Surgery). Antidiabetic drugs (oral agents and insulin) – hypoglycemia or hyperglycemia; adjust antidiabetic drug dosage accordingly (see WARNINGS, Diabetes and Hypoglycemia). Catecholamine-depleting drugs (e.g., reserpine) – additive effect; monitor closely for hypotension and/or excessive bradycardia.

Carcinogenesis, Mutagenesis, impairment of Fertility – In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy – In animal reproduction studies with nadolol, evidence of embryo-and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus. Neonates of mothers who received nadolol at parturition have exhibited bradycardia, hypoglycemia and associated symptoms.

Nursing Mothers – Nadolol is excreted in human milk. Exercise caution when nadolol is administered to a nursing woman.

Pediatric Use – Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular – Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** – Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** – Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** – Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** – Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision; infrequent reversible alopecia. The following adverse reactions have been reported in patients taking nadolol and/or other beta-adrenergic blocking agents, but no causal relationship to nadolol has been established. **Central Nervous System** – reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** – mesenteric arterial thrombosis; ischemic colitis; elevated liver enzymes. **Hematologic** – agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** – fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** – pemphigoid rash; hypertensive reaction in patients with pheochromocytoma; sleep disturbances; Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia – Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure – Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension – Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm – Administer a beta$_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; may be gradually increased in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 40 or 80 mg q.d. (doses up to 160 or 240 mg daily may be needed). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 40 or 80 mg q.d. (doses up to 240 or 320 mg daily may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and in Unimatic® unit-dose packs of 100 tablets. The 40 mg, 80 mg, and 120 mg potencies are also available in bottles of 1000 tablets. (J3-527D)

RENAL USE CLOSE

Since with increasing blood pressure there may be a progressive decline in renal blood flow,[1] prescribe . . .

CORGARD® (nadolol tablets)

Lowers blood pressure

Preserves renal blood flow

Studies prove that CORGARD (nadolol tablets) preserves renal blood flow unlike some beta-blockers, such as propranolol.[1-4]

In a two-year study of 106 patients, CORGARD also decreased serum creatinine, a measurement of improved renal function.[5]

- *Offers once-a-day convenience.*
- *Low incidence of CNS side effects.**
- *Avoids potassium depletion.*
- *Maintains long-term control.*

CORGARD®
(nadolol tablets)

STEP-1 FOR HYPERTENSION WITH ONCE-A-DAY DOSE

*For a discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, please see brief summary of prescribing information on adjacent page.

A GREAT WAY TO SERVE

1058

Only Ativan® (lorazepam) C IV

offers all these benefits in addition to rapid relief of anxiety:

relief of anxiety associated with depressive symptoms

clearance not significantly delayed by age, liver or kidney dysfunction

cumulative sedative effects seldom a problem

little likelihood of drug interaction
(all benzodiazepines produce additive effects when taken with alcohol or other CNS depressants)

no significant changes in vital signs in cardiovascular patients*

short duration of action, simple metabolism

*Benzodiazepines have not been shown to be of benefit in treating the cardiovascular component.

See important information on preceding page.

© 1985, Wyeth Laboratories

DISTINCTIVE DESIGN 0.5, 1.0 and 2.0 mg

Brief Summary of Prescribing Information.

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia, some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Transient amnesia or memory impairment has been reported in association with the use of benzodiazepines.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® (IV) for (lorazepam) Anxiety

DOSAGE: Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.

HOW SUPPLIED: 0.5, 1.0 and 2.0mg tablets.

INTERPRETATION OF CLINICAL LABORATORY TESTS—REFERENCE VALUES AND THEIR BIOLOGICAL VARIATION—Edited by Gérard Siest, PhD, Head, Laboratory Department, Center for Preventive Medicine, Vandoeuvre-les-Nancy, and Professor of Biochemical Pharmacology, University of Nancy; Joseph Henny, PhD, and Françoise Schiele, PhD, Directors, Laboratory Department, Center for Preventive Medicine, Vandoeuvre-les-Nancy, France, and Donald S. Young, MB, PhD, Department of Laboratory Medicine, Mayo Clinic and Foundation, Rochester, Minnesota. Biomedical Publications, PO Box 8209, Foster City, CA 94404, 1985. 455 pages, $42.50.

LIFETIME CARE OF THE PARAPLEGIC PATIENT—Edited by Sir George M. Bedbrook, Kt, OBE, OStJ, MS(Melb), HonMD(WA), HonFRCS(Ed), FRCS FRACS DPRM(Syd), Senior Spinal Surgeon, Royal Perth Hospital and Royal Perth Rehabilitation Hospital, Perth, Western Australia. Churchill Livingstone Inc, 1560 Broadway, New York, NY 10036, 1985. 263 pages, $55.

McALPINE'S MULTIPLE SCLEROSIS—W. B. Matthews, DM, FRCP, Professor of Clinical Neurology, University of Oxford; E. D. Acheson, MA, BCh, DM, FRCP, Chief Medical Officer, Department of Health and Social Security, Alexander Fleming House, London; J. R. Batchelor, MD, Professor of Immunology, Hammersmith Hospital, London, and R. O. Weller, BSci, MD, PhD, FRCPath, Professor of Neuropathology, University of Southampton, Southampton, UK. Churchill Livingstone Inc, 1560 Broadway, New York, NY 10036, 1985. 358 pages, $59.

MAGNETIC RESONANCE IMAGING OF THE BRAIN, HEAD, AND NECK: A TEXT—ATLAS—William G. Bradley, Jr, MD, PhD, Director, NMR Imaging Laboratory, Huntington Medical Research Institutes and Department of Radiology, Huntington Memorial Hospital, Pasadena, California, and Assistant Clinical Professor of Radiology, University of California, San Francisco; W. Ross Adey, MB, BS, MD, Associate Chief of Staff for Research and Development, Pettis Memorial Veterans' Hospital, and Professor of Physiology and Surgery, Loma Linda University School of Medicine, and Anton N. Hasso, MD, Director, Neuroradiological Section, Loma Linda University Medical Center, and Professor of Radiology, Loma Linda University School of Medicine, Loma Linda, California. Aspen Systems Corporation, 1600 Research Blvd, Rockville, MD 20850, 1985. 125 pages, $65.

MANAGING INCONTINENCE—Edited by Cheryle Gartley, Founder and President of the Simon Foundation, Wilmette, Illinois. Jameson Books, 722 Columbus St, Ottawa, IL 61350, 1985. 150 pages, $12.95.

MEDICAL MALPRACTICE—A PREVENTIVE APPROACH—William O. Robertson, MD, Professor, Department of Pediatrics, University of Washington; Head, Washington State Medical Association Risk Management Program, and Director of the Quality Assurance Program, Children's Orthopedic Hospital, Seattle. University of Washington Press, Seattle, WA 98105, 1985. 222 pages, $20.

MEDICAL SCIENCE AND THE ADVANCEMENT OF WORLD HEALTH—Edited by Robert Lanza, MD. Praeger, 521 Fifth Ave, New York, NY 10175, 1985. 271 pages, $39.95.

MEDICINE IN THE TROPICS—Second Edition—Edited by A. W. Woodruff, CMG, MD, PhD, FRCP, FRCPE, CTM&H, Professor of Medicine, University of Juba, Sudan, and Consulting Physician, Hospital for Tropical Diseases, London, and S. G. Wright, MB, MRCP(UK), Senior Lecturer, Department of Clinical Tropical Medicine, London School of Hygiene and Tropical Medicine, and Honorary Consultant Physician, Hospital for Tropical Diseases, London. Churchill Livingstone Inc, 1560 Broadway, New York, NY 10036, 1984. 636 pages, $62 (paperback).

INFORMATION FOR AUTHORS

Submitting Manuscripts

Manuscripts for consideration should be sent to the editor, Malcolm S. M. Watts, MD, 44 Gough Street, San Francisco, California 94103. The transmittal letter should designate one person as correspondent and include complete address, with ZIP code and telephone number.

In view of *The Copyright Revision Act of 1976,* transmittal letters should contain the following language: "In consideration for reviewing and editing my submission, the author(s) undersigned hereby transfers, assigns or otherwise conveys all copyright ownership to THE WESTERN JOURNAL OF MEDICINE in the event that such work is published by the journal." This statement should be signed by *all* the authors.

Authors are urged to seek clarity and succinctness in all manuscripts regardless of subject matter or format and to give close attention to syntax, grammar and spelling.

Clinical Investigation Section

Articles that authors wish to have considered for the Clinical Investigation section should be so designated in the transmittal letter. The type of articles appropriate for this section are those that describe experimental work in humans that extensively and prospectively examines scientific hypotheses relating to disease. An article describing a single case report will not normally be considered appropriate for this section.

Preparing Manuscripts

The original manuscript and *two* copies should be submitted on heavy bond paper (8½ by 11 inches, *not* erasable), typed *double-spaced throughout* (including legends, tables and references) on one side of the paper, with 1½-inch margins. Ordinarily, articles should not exceed 3,000 words (less than 15 text pages, typed double-spaced). Under exceptional circumstances only will articles longer than 4,000 words be published. Pages should be numbered consecutively, beginning with the title page.

Style

Abbreviations. Use of abbreviations should be minimized. If they are necessary, abbreviations should be spelled out at first mention, with the abbreviation itself immediately following in parentheses.

Weights and measures. All measurements should be given in metric units. English equivalents should be given parenthetically if the measurements were originally done in English units.

Temperatures. Temperature readings should be given first in Celsius, followed by the Fahrenheit equivalent in parentheses.

Drug names. If the trade name of a drug is used, the generic name should be given first, followed by the trade name in parentheses. Trade names are capitalized, generic names are not.

Title Page

Titles are best when brief and concise. The title page should include the full name of the author(s), with degrees, academic or professional titles, complete addresses and any institutional or other affiliations. The complete name and address of the person who will handle reprint requests also should appear on this page.

Abstract

The abstract (approximately 150 words) should be a short summary, saying in brief what is said at length in the body of the article—rather than such and such "is discussed," "is presented" or "was investigated."

Tables and Figures

Tables

Each table should be typed on a separate sheet of paper, be numbered consecutively in Arabic numerals, have a brief descriptive title and have its position indicated in the text.

Illustrations (Figures)

Three sets of clear, unmounted black and white glossy prints of figures should be submitted (preferably 5 by 7 inches, but no larger than 8½ by 11 inches). For line drawings, original artwork or glossy prints are acceptable. Illustrations should be numbered consecutively in Arabic numerals and their position indicated in the text. Figure number, first author's name and top of the photo should be shown on the reverse side of each illustration. Recognizable photographs of patients are to be masked and written permission for publication obtained from the patients.

Legends

All legends for figures should be typed together on a separate sheet of paper. Magnification and stain for photomicrographs should be indicated in parentheses.

Permission for Reproduction

If an illustration or table has been used previously in another publication, written permission for its use must be obtained from the publisher, and should accompany the manuscript. The source should be acknowledged in the legend if it can be done briefly by citation of a reference number. Otherwise, acknowledgment is made at the end of the figure legend or at the bottom of the table.

References

References should be limited to those cited in the text. They must be typed double-spaced and numbered consecutively as they appear in the manuscript. (See examples below for style.) Abbreviations of journal titles should conform to those used in *Index Medicus.*

Journal Articles

Note handling of multiple authorship. If more than three authors are listed as contributors, use "et al" to designate those names after the first three. Also note capitalization, punctuation, mention of inclusive page numbers and year of publication. Separate the subtitle from the title by either a dash or a colon. Use colon *only* if it appears in the original citation.

1. Jones JS, Anderson HW, Johnson DW, et al: The athletic heart revisited—Sudden death of a 28-year-old athlete. JAMA 1978; 292:444-456

2. Graybill JR, Alford RH, Smith RG, et al: Cell-mediated immunity in cryptococcosis: A brief review. Cell Immunol 1978; 7:76-79

Books

Note handling of "edition," "editor(s)," and "volume," as well as appropriate sequence of reference information and capitalization of chapters and titles.

3. Berne EJ, Smith TL: Role playing in therapy, chap 2, Principles of Group Therapy. New York, Oxford University Press, 1966, pp 35-51 *(author of chapter same as author of book)*

4. Munsung JM: The role of drugs, chap 2, *In* Brest AN, Mayer JH (Eds): Hypertension—Vol 2, Therapy, 2nd Ed. Springfield, Ill, Charles C Thomas, 1961, pp 456-479 *(author of chapter different from authors of book)*

Pamphlets, Monographs or Books With No Given Author

5. AMA Department of Drugs: AMA Drug Evaluation, 3rd Ed. Littleton, Mass, Publishing Sciences Group, 1977 *(corporate author)*

6. Compilation of Standard Definitions, 3rd Ed. Philadelphia, American Society for Testing and Materials, 1976 *(no given author; give name and place of publisher)*

Articles in Press or Accepted for Publication

Any article accepted for publication should include the name of the journal (appropriately abbreviated) in which it will appear, and the phrase "in press" or "accepted for publication" in place of the date of publication.

Personal Communications and Unpublished Data

This information should *not* be included in the reference list but should be given in parentheses in the body of the text. Date of communication, whether it was personal or written, and the person's name, highest academic degree and professional affiliation should be provided.

Acknowledgments

It is the policy of the *WJM* not to print acknowledgments, the feeling being that if a person has contributed enough to a paper to be mentioned, he or she should be included among the authors, or the contribution should be mentioned in the body of the paper or in a footnote.

Correspondence

Brief manuscripts commenting on articles that have appeared in the journal, containing information of interest to physicians or discussing issues of the day will be considered for publication. Very short reports of cases, clinical experience, clinical studies, adverse effects and the like also will be considered. Items for the Correspondence section should not exceed 600 words and should have no more than five bibliographic references and one figure or table.

Author Responsibility

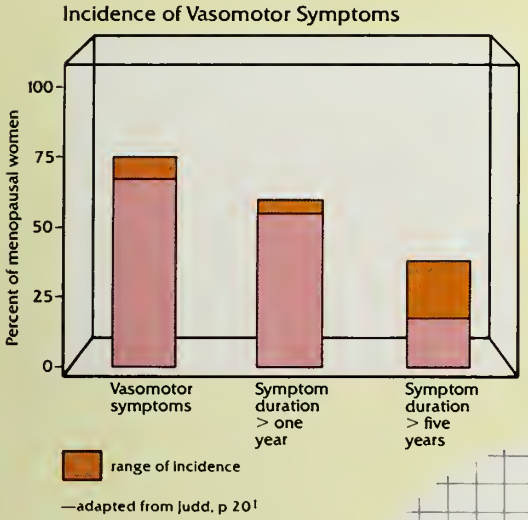
Authors are responsible for all statements made in articles. Manuscripts are considered for publication with the explicit understanding that they are original, have not been published previously and are not simultaneously under consideration by any other publication.

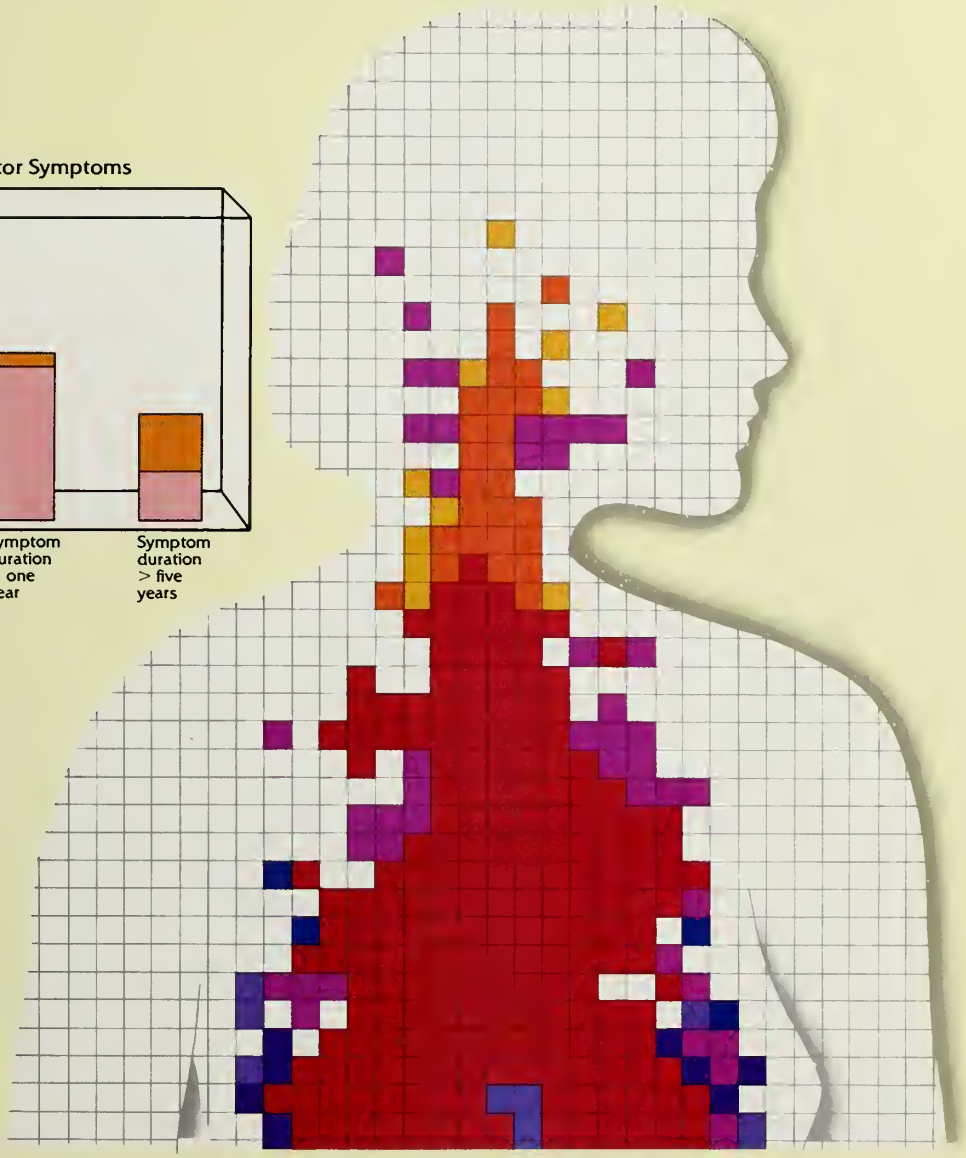
All accepted manuscripts are subject to copy editing, and authors are sent edited galleys for approval. No changes will be made after the final, edited version has been approved by the author.

Reprints

If reprints are desired, they must be paid for by the author. A reprint order form with schedule of prices is sent to the author when the article is published. Authors are responsible for handling requests for reprints of their articles.

VASOMOTOR SYMPTOMS THAT DEMAND INTERVENTION





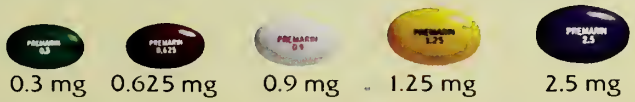
PREMARIN RELIEVES MODERATE TO SEVERE VASOMOTOR SYMPTOMS

Vasomotor symptoms are the most common manifestation of the menopause, affecting up to 75% of menopausal women. Of these, 80% may suffer for more than a year and up to 50% for more than five years! These symptoms can disrupt a woman's life by chronically interrupting sleep, resulting in anxiety and irritability.

In a study of postmenopausal women suffering severe episodes of cutaneous flushing, symptoms improved markedly after administration of estrogen[2]—the treatment of choice for moderate to severe vasomotor symptoms.[3] The estrogen of choice is PREMARIN, the most widely prescribed estrogen for over 40 years. PREMARIN (Conjugated Estrogens Tablets, U.S.P.) relieves moderate to severe vasomotor symptoms of the natural menopause, as well as the acute and often severe symptoms of surgical menopause.

PREMARIN®

(CONJUGATED ESTROGENS TABLETS, U.S.P.)



0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg

Please see last page for brief summary of full prescribing information.

VAGINAL ATROPHY THAT INTERFERES WITH SEXUALITY

PREMARIN RESTORES THE VAGINAL ENVIRONMENT

In the postmenopausal woman, decreasing levels of estrogen can have devastating effects on a woman's sexual functioning. The pH of vaginal secretions rises, promoting the growth of contaminating organisms. The vaginal epithelium dries and thins, becoming susceptible to irritation, injury, and infection. Sexual relations may be difficult or impossible.

PREMARIN (Conjugated Estrogens, U.S.P.) Vaginal Cream focuses therapy at the site of the problem. Vaginal dryness is relieved, pH reverts to its normal acidity, and the epithelium thickens and becomes more resistant to injury and infection. With the vaginal environment returned to its premenopausal state, sexual function may improve.

PREMARIN®

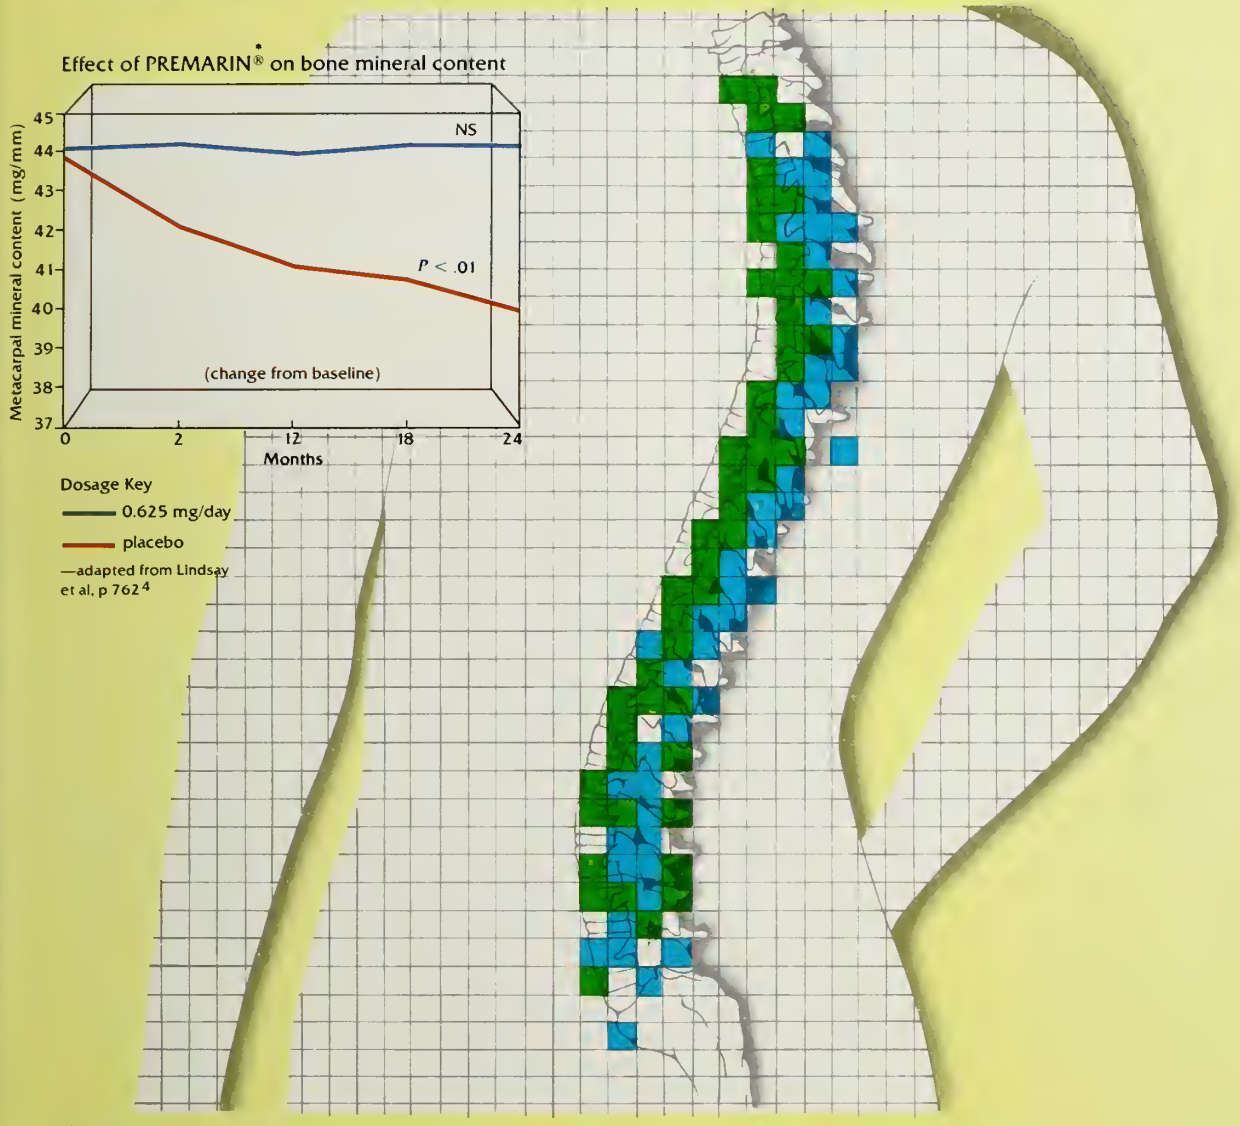
Please see last page for brief summary of full prescribing information.

POSTMENOPAUSAL BONE LOSS THAT INCAPACITATES



PREMARIN MAY HALT THE DISABLING COURSE OF OSTEOPOROSIS*

Osteoporosis has an enormous epidemiological impact: it affects 10 million American women, and 26% of all women over age 60.[5] The disease begins silently and progresses inexorably for 15 to 20 years, until disabling complications occur.[6]

To minimize osteoporotic damage, the condition must be detected early and treated promptly. For many patients, PREMARIN is optimal therapy for osteoporosis, as part of a comprehensive program that includes exercise, good nutrition, and calcium supplements. In a controlled study of postmenopausal and oophorectomized women, PREMARIN (Conjugated Estrogens Tablets, U.S.P.) doses of 0.625 mg/day prevented loss of metacarpal mineral content (see graph above).[4]

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)

0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg

*Conjugated Estrogens Tablets have been evaluated as probably effective for estrogen-deficiency-induced osteoporosis.

Please see last page for brief summary of full prescribing information.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR)*

PREMARIN® Brand of Conjugated Estrogens Tablets, U.S.P.

PREMARIN® Brand of Conjugated Estrogens, U.S.P. Vaginal Cream in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA.

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (Conjugated Estrogens, U.S.P.) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters.

INDICATIONS: Based on a review of PREMARIN Tablets by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications for use as follows:

Effective: 1. Moderate to severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms, and they should not be used to treat such conditions.)

2. Atrophic vaginitis
3. Kraurosis vulvae
4. Female hypogonadism
5. Female castration
6. Primary ovarian failure
7. Breast cancer (for palliation only) in appropriately selected women and men with metastatic disease.
8. Prostatic carcinoma—palliative therapy of advanced disease.
9. Postpartum breast engorgement—Although estrogens have been widely used for the prevention of postpartum breast engorgement, controlled studies have demonstrated that the incidence of significant painful engorgement in patients not receiving such hormonal therapy is low and usually responsive to appropriate analgesic or other supportive therapy. Consequently, the benefit to be derived from estrogen therapy for this indication must be carefully weighed against the potential increased risk of puerperal thromboembolism associated with the use of large doses of estrogens.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

"Probably" effective: For estrogen deficiency-induced osteoporosis, and only when used in conjunction with other important therapeutic measures such as diet, calcium, physiotherapy, and good general health-promoting measures. Final classification of this indication requires further investigation.

INDICATIONS: PREMARIN (Conjugated Estrogens, U.S.P.) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae. PREMARIN Vaginal Cream HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (See Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Long term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There are now reports that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.) At the present time there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast, although a recent study has raised this possibility. There is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives. Increased blood pressure may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Oral contraceptives appear to be associated with an increased incidence of mental depression. Patients with a history of depression should be carefully observed. Preexisting uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not complete.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.

b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability.

c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.

d. Impaired glucose tolerance.

e. Decreased pregnanediol excretion.

f. Reduced response to metyrapone test.

g. Reduced serum folate concentration.

h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued; erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair; hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria; edema; changes in libido.

ACUTE OVERDOSAGE. May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of Conjugated Estrogens Tablets, U.S.P.

1. *Given cyclically for short-term use only.* For treatment of moderate to severe vasomotor symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three to six month intervals.

2. *Given cyclically:* Female hypogonadism. Female castration. Primary ovarian failure. Osteoporosis.

Female hypogonadism—2.5 to 7.5 mg daily, in divided doses for 20 days, followed by a rest period of 10 days' duration. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium.

If bleeding occurs before the end of the 10 day period, begin a 20 day estrogen-progestin cyclic regimen with PREMARIN (Conjugated Estrogens Tablets, U.S.P.), 2.5 to 7.5 mg daily in divided doses, for 20 days. During the last five days of estrogen therapy, give an oral progestin. If bleeding occurs before this regimen is concluded, therapy is discontinued and may be resumed on the fifth day of bleeding.

Female castration and primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis (to retard progression)—1.25 mg daily, cyclically.

3. *Given for a few days:* Prevention of postpartum breast engorgement—3.75 mg every four hours for five doses, or 1.25 mg every four hours for five days.

4. *Given chronically:* Inoperable progressing prostatic cancer—1.25 to 2.5 mg three times daily.

Inoperable progressing breast cancer in appropriately selected men and postmenopausal women—10 mg three times daily for a period of at least three months.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

PREMARIN® Brand of Conjugated Estrogens, U.S.P. Vaginal Cream

Given cyclically for short-term use only. For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three to six month intervals.

Usual dosage range: 2 to 4 g daily, intravaginally or topically, depending on the severity of the condition.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED: PREMARIN (Conjugated Estrogens Tablets, U.S.P.). No. 865—Each *purple* tablet contains 2.5 mg in bottles of 100 and 1,000. No. 866—Each *yellow* tablet contains 1.25 mg in bottles of 100 and 1,000. Also in Cycle Pack of 21 and in unit dose package of 100. No. 864—Each *white* tablet contains 0.9 mg in bottles of 100. Also in Cycle Pack of 21. No. 867—Each *maroon* tablet contains 0.625 mg in bottles of 100 and 1,000. Also in Cycle Pack of 21 and unit dose package of 100. No. 868—Each *green* tablet contains 0.3 mg in bottles of 100 and 1,000. The appearance of these tablets is a trademark of Ayerst Laboratories.

PREMARIN (Conjugated Estrogens, U.S.P.) Vaginal Cream—No. 872—Each gram contains 0.625 mg Conjugated Estrogens, U.S.P. (Also contains cetyl esters wax, cetyl alcohol, white wax, glyceryl monostearate, propylene glycol monostearate, methyl stearate, phenylethyl alcohol, sodium lauryl sulfate, glycerin, and mineral oil.)

Combination package: Each contains Net Wt. 1½ oz. (42.5 g) tube with one calibrated plastic applicator.

Also Available—Refill package: Each contains Net Wt. 1½ oz. (42.5 g) tube. **4340R2/785**

SCPIE.
An enviable record of healthy growth and achievement.

In Perfect Health!

That's the professional opinion on SCPIE.

By every key test, SCPIE is strong...

Best's, the highly-respected, independent, national insurance rating bureau, has just given SCPIE its first rating, "A" (Excellent).

Assets: SCPIE has more assets than any other physician-owned company in California.

Reserves: SCPIE has reserves to pay all outstanding and anticipated claims.

Surplus: SCPIE maintains an adequate surplus as a cushion against unexpected losses.

Membership: SCPIE is strong and growing, with more members in Southern California than any other company.

Management: SCPIE's all-physician Board of Governors and professional insurance staff have proven that conservative management pays off.

Underwriting: Physician control helps keep losses down.

Why is SCPIE the leader?

SCPIE has the lowest overhead of any physician-owned company in Southern California.

For the sixth year, SCPIE is repaying the Capital Contributions which physicians put up to start the company.

Returns of Capital Contributions are approved by the State Department of Insurance—further confirmation of SCPIE's strength.

SCPIE returns premium and investment income not needed to pay claims and expenses. In 1985 SCPIE is returning $7 million as Experience Credits for policy years 1976-81. This makes significant reductions in net premiums.

SCPIE is here to stay.

SCPIE has become the seventh largest writer of medical liability coverage in the entire nation. An enviable record of healthy growth and achievement.

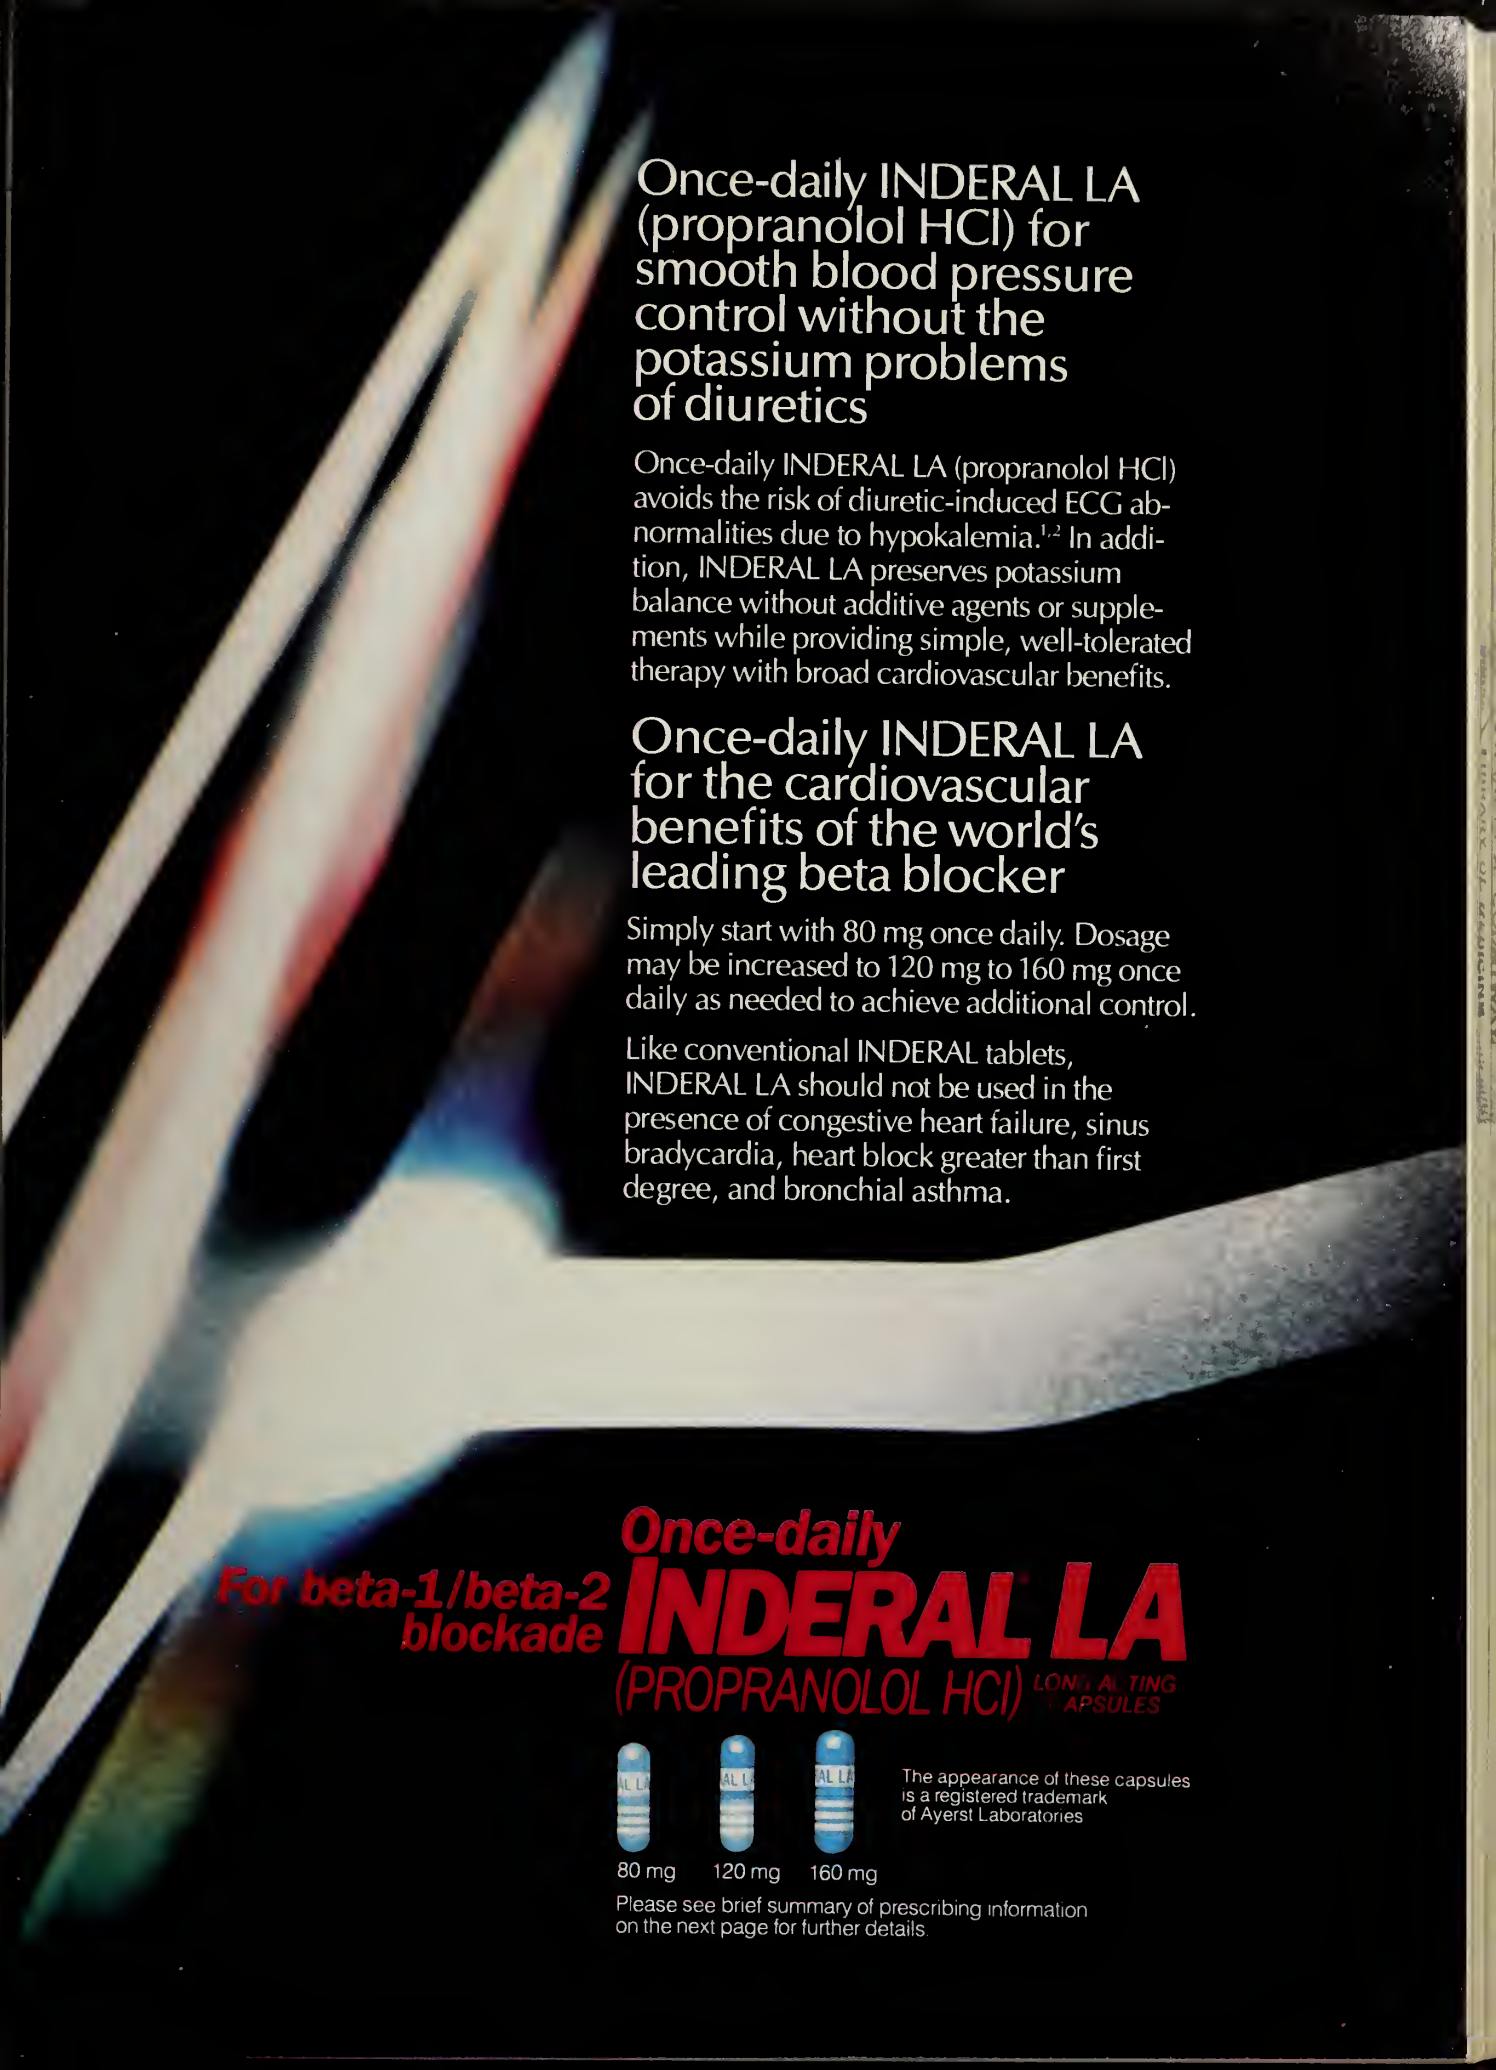
Right from the start in hypertension...



Once-daily INDERAL LA (propranolol HCl) for smooth blood pressure control without the potassium problems of diuretics

Once-daily INDERAL LA (propranolol HCl) avoids the risk of diuretic-induced ECG abnormalities due to hypokalemia.[1,2] In addition, INDERAL LA preserves potassium balance without additive agents or supplements while providing simple, well-tolerated therapy with broad cardiovascular benefits.

Once-daily INDERAL LA for the cardiovascular benefits of the world's leading beta blocker

Simply start with 80 mg once daily. Dosage may be increased to 120 mg to 160 mg once daily as needed to achieve additional control.

Like conventional INDERAL tablets, INDERAL LA should not be used in the presence of congestive heart failure, sinus bradycardia, heart block greater than first degree, and bronchial asthma.

For beta-1/beta-2 blockade

Once-daily

INDERAL LA

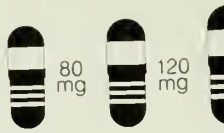
(PROPRANOLOL HCl) LONG ACTING CAPSULES

80 mg 120 mg 160 mg

The appearance of these capsules is a registered trademark of Ayerst Laboratories

Please see brief summary of prescribing information on the next page for further details.

Once-daily
For beta-1/beta-2 blockade INDERAL® LA
(PROPRANOLOL HCl) LONG ACTING CAPSULES



The appearance of these capsules is a registered trademark of Ayerst Laboratories

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*

INDERAL® LA brand of propranolol hydrochloride **(Long Acting Capsules)**

DESCRIPTION. Inderal LA is formulated to provide a sustained release of propranolol hydrochloride. Inderal LA is available as 80 mg, 120 mg and 160 mg capsules

CLINICAL PHARMACOLOGY. INDERAL is a nonselective beta-adrenergic receptor blocking agent possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available receptor sites. When access to beta-receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

INDERAL LA Capsules (80, 120, and 160 mg) release propranolol HCl at a controlled and predictable rate. Peak blood levels following dosing with INDERAL LA occur at about 6 hours and the apparent plasma half-life is about 10 hours. When measured at steady state over a 24-hour period the areas under the propranolol plasma concentration-time curve (AUCs) for the capsules are approximately 60% to 65% of the AUCs for a comparable divided daily dose of INDERAL tablets. The lower AUCs for the capsules are due to greater hepatic metabolism of propranolol, resulting from the slower rate of absorption of propranolol. Over a twenty-four (24) hour period, blood levels are fairly constant for about twelve (12) hours then decline exponentially.

INDERAL LA should not be considered a simple mg for mg substitute for conventional propranolol and the blood levels achieved do not match (are lower than) those of two to four times daily dosing with the same dose. When changing to INDERAL LA from conventional propranolol, a possible need for retitration upwards should be considered especially to maintain effectiveness at the end of the dosing interval. In most clinical settings, however, such as hypertension or angina where there is little correlation between plasma levels and clinical effect, INDERAL LA has been therapeutically equivalent to the same mg dose of conventional INDERAL as assessed by 24-hour effects on blood pressure and on 24-hour exercise responses of heart rate, systolic pressure and rate pressure product. INDERAL LA can provide effective beta blockade for a 24-hour period.

The mechanism of the antihypertensive effect of INDERAL has not been established. Among the factors that may be involved in contributing to the antihypertensive action are (1) decreased cardiac output, (2) inhibition of renin release by the kidneys, and (3) diminution of tonic sympathetic nerve outflow from vasomotor centers in the brain. Although total peripheral resistance may increase initially, it readjusts to or below the pretreatment level with chronic use. Effects on plasma volume appear to be minor and somewhat variable. INDERAL has been shown to cause a small increase in serum potassium concentration when used in the treatment of hypertensive patients.

In angina pectoris, propranolol generally reduces the oxygen requirement of the heart at any given level of effort by blocking the catecholamine-induced increases in the heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. Propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure and systolic ejection period. The net physiologic effect of beta-adrenergic blockade is usually advantageous and is manifested during exercise by delayed onset of pain and increased work capacity.

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential. The significance of the membrane action in the treatment of arrhythmias is uncertain.

The mechanism of the antimigraine effect of propranolol has not been established. Beta-adrenergic receptors have been demonstrated in the pial vessels of the brain.

Beta receptor blockade can be useful in conditions in which, because of pathologic or functional changes, sympathetic activity is detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block greater than first degree, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

Propranolol is not significantly dialyzable.

INDICATIONS AND USAGE. Hypertension: INDERAL LA is indicated in the management of hypertension; it may be used alone or used in combination with other antihypertensive agents, particularly a thiazide diuretic. INDERAL LA is not indicated in the management of hypertensive emergencies.

Angina Pectoris Due to Coronary Atherosclerosis: INDERAL LA is indicated for the long-term management of patients with angina pectoris.

Migraine: INDERAL LA is indicated for the prophylaxis of common migraine headache. The efficacy of propranolol in the treatment of a migraine attack that has started has not been established and propranolol is not indicated for such use.

Hypertrophic Subaortic Stenosis: INDERAL LA is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL LA also improves exercise performance. The effectiveness of propranolol hydrochloride in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta-receptor stimulation. Clinical improvement may be temporary.

CONTRAINDICATIONS. INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma, 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS. CARDIAC FAILURE. Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary, they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely; or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks, and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)— PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY. The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL (propranolol HCl), like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA. Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS. Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS. *General.* Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL (propranolol HCl) is not indicated for the treatment of hypertensive emergencies.

Beta adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests. Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS. Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility. Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy. Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS. Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular. bradycardia, congestive heart failure, intensification of AV block, hypotension, paresthesia of hands, thrombocytopenic purpura, arterial insufficiency, usually of the Raynaud type.

Central Nervous System. lightheadedness, mental depression manifested by insomnia, lassitude, weakness, fatigue, reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal. nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic. pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory. bronchospasm.

Hematologic. agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune. In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous. alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

DOSAGE AND ADMINISTRATION. INDERAL LA provides propranolol hydrochloride in a sustained-release capsule for administration once daily. If patients are switched from INDERAL tablets to INDERAL LA capsules, care should be taken to assure that the desired therapeutic effect is maintained. INDERAL LA should not be considered a simple mg for mg substitute for INDERAL. INDERAL LA has different kinetics and produces lower blood levels. Retitration may be necessary especially to maintain effectiveness at the end of the 24-hour dosing interval.

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 80 mg INDERAL LA once daily, whether used alone or added to a diuretic. The dosage may be increased to 120 mg once daily or higher until adequate blood pressure control is achieved. The usual maintenance dosage is 120 to 160 mg once daily. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 80 mg INDERAL LA once daily, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg once daily. In angina pectoris the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of a few weeks (see WARNINGS).

MIGRAINE—*Dosage must be individualized.* The initial oral dose is 80 mg INDERAL LA once daily. The usual effective dose range is 160-240 mg once daily. The dosage may be increased gradually to achieve optimum migraine prophylaxis. If a satisfactory response is not obtained within four to six weeks after reaching the maximum dose, INDERAL LA therapy should be discontinued. It may be advisable to withdraw the drug gradually over a period of several weeks.

HYPERTROPHIC SUBAORTIC STENOSIS—80-160 mg INDERAL LA once daily.

PEDIATRIC DOSAGE—At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

New Motrin® 800 TABLETS mg

ibuprofen

a stronger reason to prescribe Motrin Tablets

© 1985 The Upjohn Company

New Motrin® 800 TABLETS mg
ibuprofen

Extra-Strength Motrin Tablets— a convenient way to tap the full potential of Motrin:

The newest strength of *Motrin* Tablets

makes treatment easier for arthritis patients who need the doses that provide higher levels of anti-inflammatory activity as well as potent analgesia...just 1 tablet t.i.d. provides 2400 mg/day.

expands the dosage convenience of MOTRIN Tablets—makes it even easier to adjust the dosage of MOTRIN to each patient's needs...the new dosage range of up to 3200 mg/day can be achieved on a q.i.d. regimen. Gastroscopic studies at varying doses show an increased tendency toward gastric irritation at higher doses. However, at comparable doses, gastric irritation is about half that seen with aspirin.

provides economy...patients should pay less for MOTRIN Tablets than comparable dosages of Clinoril, Feldene, or Naprosyn.

provides, above all, the experience-proven efficacy and safety profile of *Motrin.* MOTRIN continues to be America's most often prescribed nonsteroidal anti-inflammatory agent.

Please turn the page for a brief summary of prescribing information.

Upjohn

The Upjohn Company, Kalamazoo, Michigan 49001

Motrin® Tablets
(ibuprofen)
Indications and Usage: Treatment of signs and symptoms of rheumatoid arthritis and osteoarthritis. Relief of mild to moderate pain and primary dysmenorrhea. Safety and efficacy in children are not established
Contraindications: Anaphylactoid reactions have occurred in individuals hypersensitive to MOTRIN or with the syndrome of nasal polyps, angioedema and bronchospastic reactivity to aspirin or other nonsteroidal anti-inflammatory agents.
Warnings: Peptic ulceration and GI bleeding, sometimes severe, have been reported. Ulceration, perforation and bleeding may end fatally. An association has not been established. Use MOTRIN under close supervision in patients with a history of upper gastrointestinal tract disease, after consulting ADVERSE REACTIONS. In patients with active peptic ulcer and active rheumatoid arthritis, try nonulcerogenic drugs, such as gold. If MOTRIN is used, observe the patient closely for signs of ulcer perforation or GI bleeding.
Chronic studies in rats and monkeys have shown mild renal toxicity with papillary edema and necrosis. Renal papillary necrosis has rarely been shown in humans treated with MOTRIN.
Precautions: Blurred and/or diminished vision, scotomata, and/or changes in color vision have been reported. If these develop, discontinue MOTRIN and the patient should have an ophthalmologic examination, including central visual fields and color vision testing.
Fluid retention and edema have been associated with MOTRIN; use with caution in patients with a history of cardiac decompensation or hypertension. In patients with renal impairment, reduced dosage may be necessary. Prospective studies of MOTRIN safety in patients with chronic renal failure have not been done.
MOTRIN can inhibit **platelet aggregation** and prolong bleeding time. Use with caution in persons with intrinsic coagulation defects and on anticoagulant therapy.
Patients should report signs or symptoms of **gastrointestinal ulceration** or bleeding, blurred vision, skin rash, weight gain, or edema. Patients on prolonged **corticosteroid therapy** should have therapy tapered slowly when MOTRIN is added.
The antipyretic, anti-inflammatory activity of MOTRIN may mask inflammation and fever.
As with other nonsteroidal anti-inflammatory drugs, borderline elevations of liver tests may occur in up to 15% of patients. These abnormalities may progress, may remain essentially unchanged, or may be transient with continued therapy. Meaningful elevations of SGPT or SGOT (AST) occurred in controlled clinical trials in less than 1% of patients. Severe hepatic reactions, including jaundice and cases of fatal hepatitis, have been reported with ibuprofen as with other nonsteroidal anti-inflammatory drugs. If liver disease develops or if systemic manifestations occur (eg, eosinophilia, rash, etc.), MOTRIN should be discontinued.
In cross-study comparisons with 1200 mg to 3200 mg daily for several weeks, a slight dose-response decrease in hemoglobin/hematocrit was noted. The total decrease in hemoglobin usually does not exceed 1 gram.
Drug interactions—*Aspirin:* used concomitantly may decrease MOTRIN blood levels.
Coumarin: bleeding has been reported in patients taking MOTRIN and coumarin.
Pregnancy and nursing mothers: MOTRIN should not be taken during pregnancy or by nursing mothers.
Adverse Reactions: The most frequent type of adverse reaction occurring with MOTRIN is gastrointestinal, of which one or more occurred in 4% to 16% of the patients. Reported side effects were higher at 3200 than at 2400 mg/day or less.
Incidence Greater Than 1% (but less than 3%)—Probable Causal Relationship
Gastrointestinal: Nausea,* epigastric pain,* heartburn,* diarrhea, abdominal distress, nausea and vomiting, indigestion, constipation, abdominal cramps or pain, fullness of GI tract (bloating and flatulence); **Central Nervous System:** Dizziness,* headache, nervousness; **Dermatologic:** Rash* (including maculopapular type), pruritus; **Special Senses:** Tinnitus; **Metabolic/Endocrine:** Decreased appetite; **Cardiovascular:** Edema, fluid retention (generally responds promptly to drug discontinuation; see PRECAUTIONS).
Incidence Less Than 1%—Probable Causal Relationship**
Gastrointestinal: Gastric or duodenal ulcer with bleeding and/or perforation, gastrointestinal hemorrhage, melena, gastritis, hepatitis, jaundice, abnormal liver function tests; **Central Nervous System:** Depression, insomnia, confusion, emotional lability, somnolence, aseptic meningitis with fever and coma; **Dermatologic:** Vesiculobullous eruptions, urticaria, erythema multiforme, Stevens-Johnson syndrome, alopecia; **Special Senses:** Hearing loss, amblyopia (blurred and/or diminished vision, scotomata, and/or changes in color vision) (see PRECAUTIONS); **Hematologic:** Neutropenia, agranulocytosis, aplastic anemia, hemolytic anemia (sometimes Coombs positive), thrombocytopenia with or without purpura, eosinophilia, decreases in hemoglobin and hematocrit (see PRECAUTIONS); **Cardiovascular:** Congestive heart failure in patients with marginal cardiac function, elevated blood pressure, palpitations; **Allergic:** Syndrome of abdominal pain, fever, chills, nausea and vomiting; anaphylaxis; bronchospasm (see CONTRAINDICATIONS); **Renal:** Acute renal failure in patients with pre-existing significantly impaired renal function, decreased creatinine clearance, polyuria, azotemia, cystitis, hematuria; **Miscellaneous:** Dry eyes and mouth, gingival ulcer, rhinitis.
Incidence Less Than 1%—Causal Relationship Unknown**
Gastrointestinal: Pancreatitis; **Central Nervous System:** Paresthesias, hallucinations, dream abnormalities, pseudotumor cerebri; **Dermatologic:** Toxic epidermal necrolysis, photoallergic skin reactions; **Special Senses:** Conjunctivitis, diplopia, optic neuritis, cataracts; **Hematologic:** Bleeding episodes (eg, epistaxis, menorrhagia); **Metabolic/Endocrine:** Gynecomastia, hypoglycemic reaction, acidosis; **Cardiovascular:** Arrhythmias (sinus tachycardia, sinus bradycardia); **Allergic:** Serum sickness, lupus erythematosus syndrome, Henoch-Schonlein vasculitis, angioedema; **Renal:** Renal papillary necrosis.
Overdosage: In cases of acute overdosage, the stomach should be emptied. The drug is acidic and excreted in the urine so alkaline diuresis may be beneficial.
Dosage and Administration: Do not exceed 3200 mg/day.
Rheumatoid arthritis and osteoarthritis: Suggested dosage is 1200 to 3200 mg per day (400, 600 or 800 mg t.i.d. or q.i.d.). The smallest effective dosage should be used. Mild to moderate pain: 400 mg every 4 to 6 hours as necessary.
How Supplied:

MOTRIN Tablets, 400 mg (orange)	MOTRIN Tablets, 600 mg (peach)	MOTRIN Tablets, 800 mg (apricot)
Bottles of 500	Bottles of 500	Bottles of 100
Unit-dose package of 100	Unit-dose package of 100	Bottles of 500
Unit of Use bottles of 100	Unit of Use bottles of 100	

Caution: Federal law prohibits dispensing without prescription. *For additional product information, see your Upjohn representative or consult the package insert.*
*Reactions occurring in 3% to 9% of patients treated with MOTRIN. (Those reactions occurring in less than 3% of the patients are unmarked.)
**Reactions are classified under *"Probable Causal Relationship (PCR)"* if there has been one positive rechallenge or if three or more cases occur which might be causally related. Reactions are classified under *"Causal Relationship Unknown"* if seven or more events have been reported but the criteria for PCR have not been met.

CONTINUING MEDICAL EDUCATION

(Continued from Page 27)

tact: Ryals and Associates, PO Box 610203, DFW Airport, TX 75261. (214) 659-9590.

September 3-6—**The Physics and Biology of Radiology: A Review Course for Diagnostic and Therapy Residents.** UCSD at Town and Country Hotel, San Diego. Tuesday-Friday. 24 hrs. Contact: Ryals and Associates, PO Box 610203, DFW Airport, TX 75261. (214) 659-9590.

September 5-8—**Physics of Diagnostic Radiology.** UCD at Davis. Thursday-Sunday. 25 hrs.

September 7—**12th Annual Radiology Symposium: Endourology/Abscess Localization and Ectopic Pregnancy.** Southern California Permanente at Airport Hilton, Los Angeles. Saturday. Contact: Lilia M. Guerrero, Southern California Kaiser-Permanente, 4747 Sunset Blvd., Los Angeles, CA 90027. (213) 667-4241.

SPORTS MEDICINE

July 28-August 1—**Marine and Aquatic Sports Medicine.** UCD at Monterey. Sunday-Thursday.

SURGERY

August 16-18—**Summer Conference on Allergy, Rheumatology and Orthopedic Surgery.** Scripps Clinic and Research Foundation at La Jolla Museum of Contemporary Art, La Jolla. Friday-Sunday. 14 hrs. Fee: $25-$195. Contact: Bonny A. Mower, Scripps Clinic, 10666 N. Torrey Pines Rd., La Jolla, CA 92037.

September 4-7—**Superficial Anatomy and Cutaneous Surgery for Dermatologists.** UCSD at San Diego. Wednesday-Saturday. 22.5 hrs.

September 18-21—**A Cementless 'Revolution' in Joint Replacement, 1985.** UCLA Extension at Los Angeles. Wednesday-Saturday. 27 hrs. Fee: $100-$475. Contact: UCLA Extension, PO Box 24901, Los Angeles, CA 90024. (213) 825-7186.

OF INTEREST TO ALL PHYSICIANS

August 6-8—**Dermatopharmacology Symposium.** Stanford at Stanford. Tuesday-Thursday.

August 10-11—**Life Review Through the Journal Process.** UCLA Extension at Los Angeles. Saturday-Sunday. Fee: $85. Contact: UCLA Extension, PO Box 24901, Los Angeles, CA 90024. (213) 825-2301.

August 17-18—**Clinical Hypnotherapy for Professionals.** UCLA Extension at Los Angeles. Saturday-Sunday. Fee: $95. Contact: UCLA Extension, PO Box 24901, Los Angeles, CA 90024. (213) 825-2301.

August 17-23—**Fine Needle Aspiration.** UCSF at Marriott Biltmore, Santa Barbara. Saturday-Friday. Fee: $525.

August 21-25—**26th Annual Advanced Seminars in Dermatology.** UCSD at Sheraton Harbor Island West, San Diego. Wednesday-Sunday. 16 hrs.

September 9-13—**Primary Care.** UCSF at Sir Francis Drake, San Francisco. Monday-Friday.

September 11-12—**Perspective on Clinical Nutritution (1985 Postgraduate Course).** American Society for Parenteral and Enteral Nutrition at Cathedral Hill Hotel, San Francisco. Wednesday-Thursday. Contact: ASPEN, 8605 Cameron St., Ste. 500, Silver Spring, MD 20910. (301) 587-6315.

September 12-13—**Monoclonal Antibodies: Diagnostic & Therapeutic Uses in Tumors and Transplantation.** UCD at Hyatt Union Square, San Francisco. Thursday-Friday.

September 12-14—**Kids Have Bones, Too.** UCD at Beverly Garland, Sacramento. Thursday-Saturday.

September 18-19—**53rd Annual Fall Symposium.** American Heart Association at Wilshire Blvd. Hilton, Los Angeles. Wednesday-Thursday. 13 hrs. Fee: $100-$185. Contact: Marianne Joyce, AHA, Greater Los Angeles Affiliate. (213) 385-4231.

September 18-20—**Adolescent and Family Treatment: An Investment for the Future.** The McDonald Center for Alcoholism and Drug Addiction Treatment Center of Scripps Memorial Hospital at Vacation Village Hotel, San Diego. Wednesday-Friday. Fee: $190. Contact: Nomi Feldman, 3770 Tansy, San Diego, CA 92121. (619) 454-6222.

September 19-22—**International Sex Research Conference/1985 Annual Conference.** The Society for the Scientific Study of Sex, Inc. at Holiday Inn Embarcadero, San Diego. Thursday-Sunday. 14 hrs. Contact: Dwight Dixon, PhD, PO Box 9902, San Diego, 92109. (619) 276-3616.

September 23-27—**Postgraduate Institute for Emergency Physicians: Symposium I.** UCSD. Monday-Friday. 13-33 hrs. Fee: $215-440.

September 26-28—**1985 Pacific Occupational Safety and Health Conference** at Le Baron Hotel, San Jose. Thursday-Saturday. Contact: Duke Hughes, POSH '85, PO Box 4420, Santa Clara, CA 95054. (408) 988-1111.

September 27-28—**40th Annual Merritt Hospital Medical Staff Seminar: Medicine, 1985.** Samuel Merritt Hospital at Kaiser Center and Merritt Hospital, Oakland. Friday-Saturday. 10 hrs. Fee: $20. Contact: Patricia R. Napp, Med. Staff Support Services, Merritt Peralta, Hawthorne Ave. & Webster St., Oakland, CA 94609. (415) 655-4000.

September 28-29—**The Skin From A to Z.** UCSF at Holiday Inn, Napa Valley. Saturday-Sunday.

September 29-October 2—**Symposium on Prevention of Osteoporosis.** University of Hawaii at Westin Ilikai Hotel, Honolulu. Sunday-Wednesday. 13.5 hrs. Fee: $300. Contact: Dr Philip Ross, Osteoporosis Center, Kuakini Medical Center, 347 N. Kaukini St., Honolulu, HI 96817. (808) 547-9578.

IDAHO

July 19-25—**Up-to-Date Cardiac Therapy.** Salmon River, Idaho White Water Rafting. Friday-Thursday. 24 hrs. Cat. I. Sponsors: University of Arizona College of Medicine and Epic Medical Expeditions. Contact: Richard Paris, MD, PO Box 209, Sun Valley 83353. (208) 788-4995.

July 21-28—**Computers in Professional Practice and Financial Planning.** Sun Valley. One week. 24 hrs. Cat I. Sponsors: University of Arizona College of Medicine and Epic Medical Expeditions. Contact: Richard Paris, MD, PO Box 209, Sun Valley 83353. (208) 788-4995.

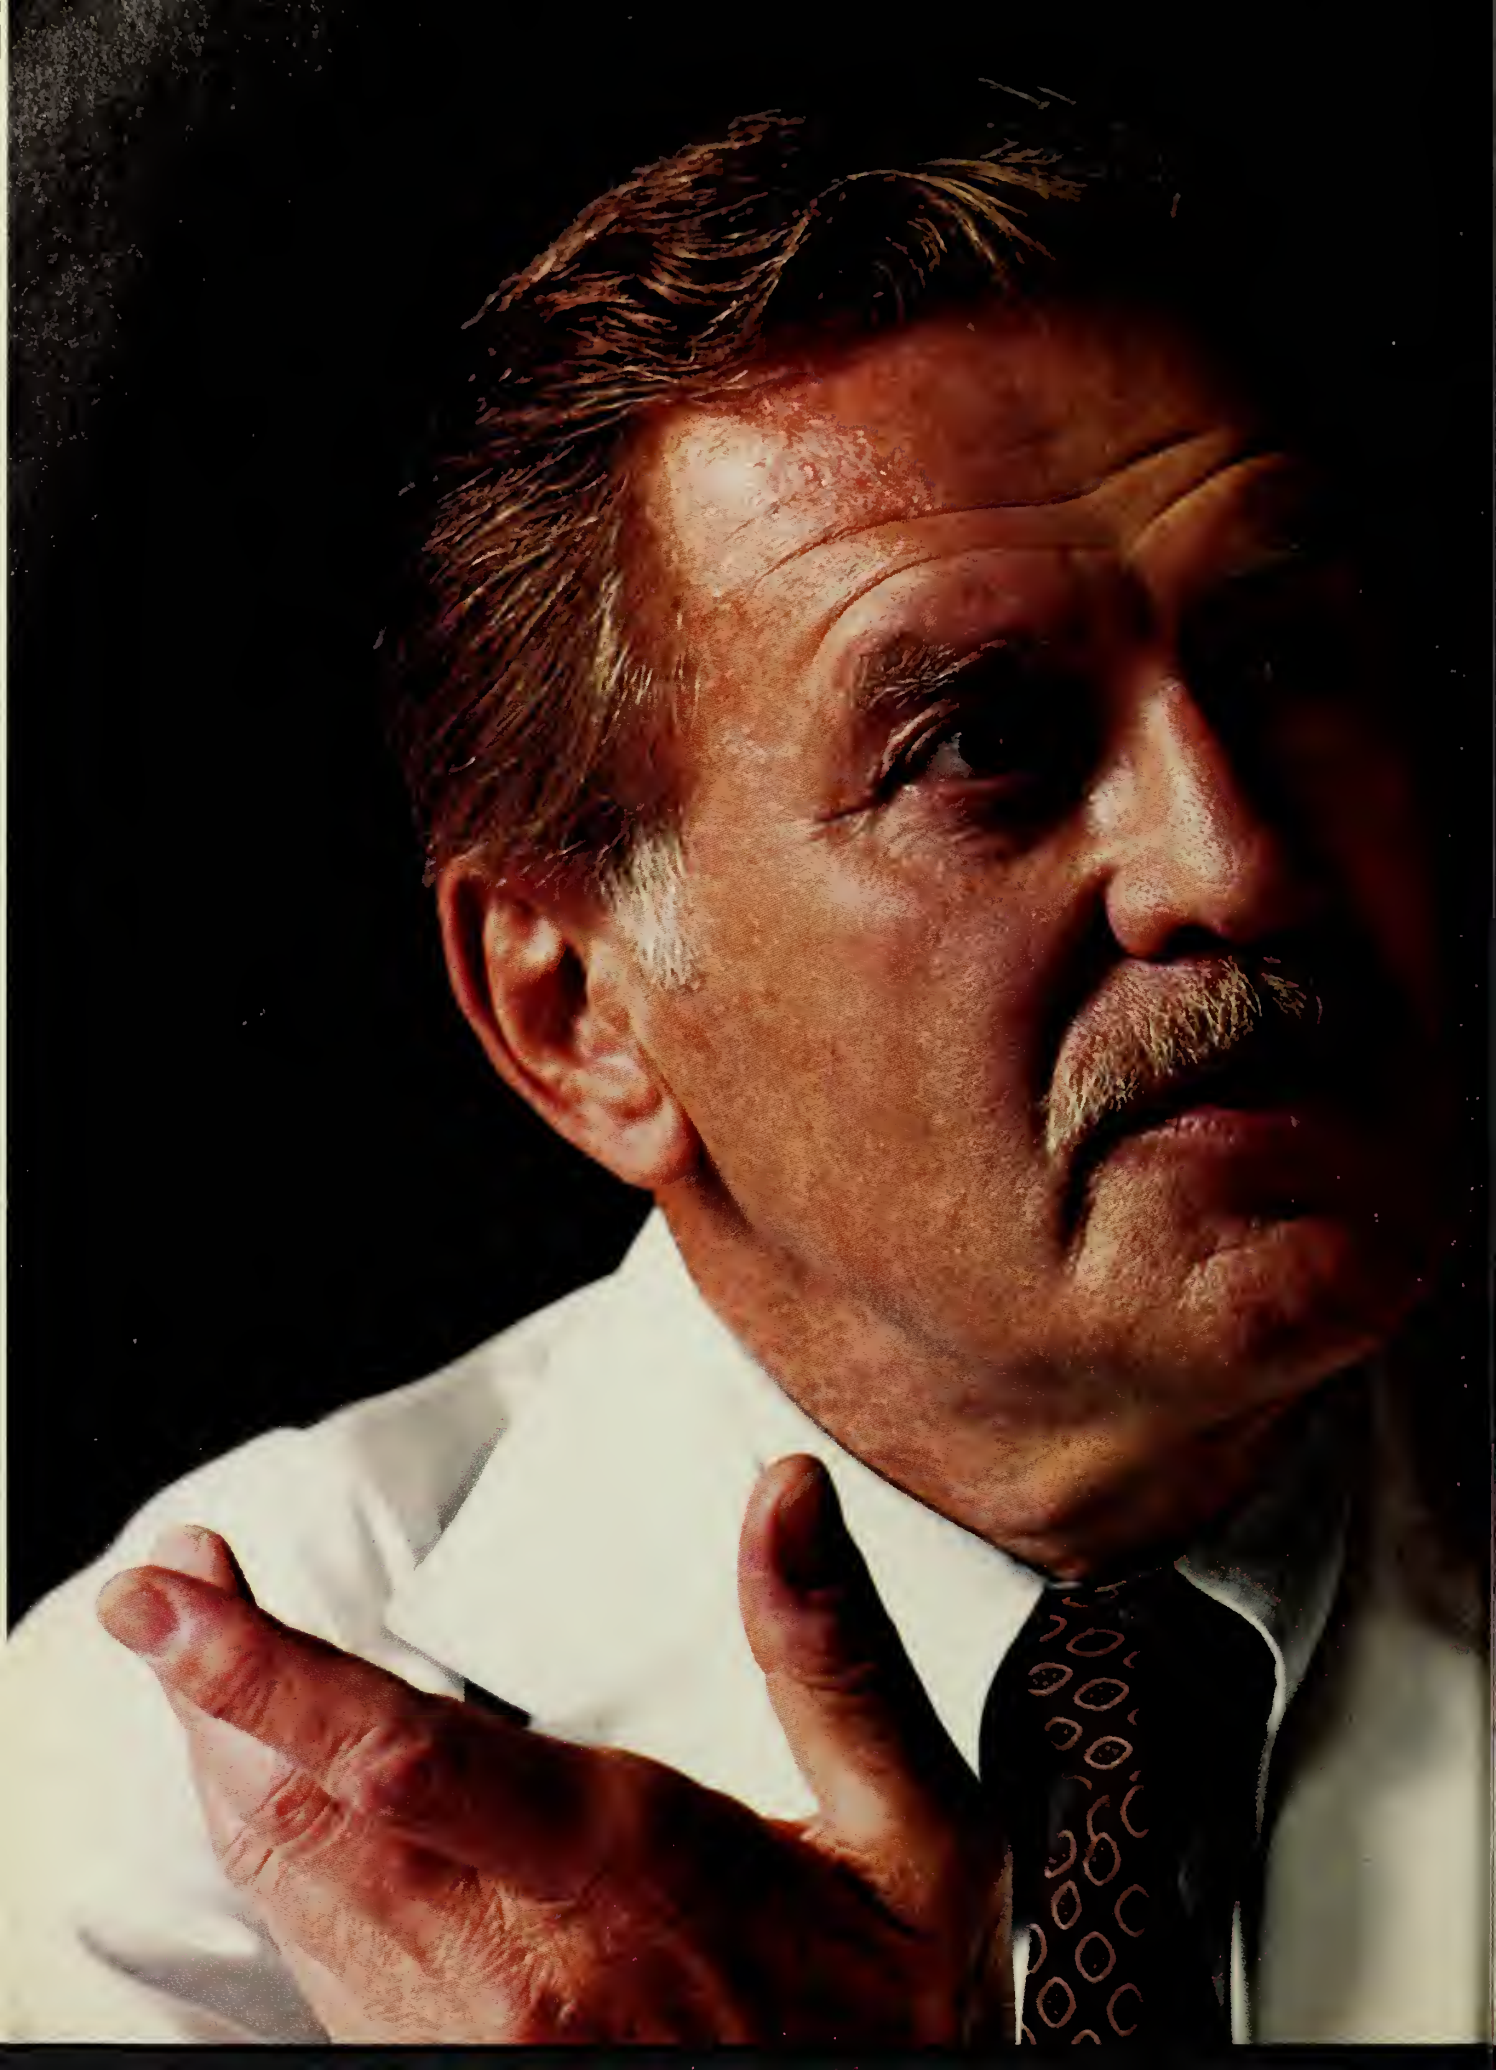
July 24-27—**Idaho Medical Association Annual Meeting.** Sun Valley. Wednesday-Saturday. Contact: IMA, PO Box 2668, Boise 83701. (208) 344-7888.

August 3-9—**Selected Topics in Wilderness and Environmental Medicine.** Mt. Bike Tour, McCall, Idaho. Saturday-Friday. 24 hrs. Cat. I. Sponsors: University of Arizona College of Medicine and Epic Medical Expeditions. Contact: Richard Paris, MD, PO Box 209, Sun Valley 83353. (208) 788-4995.

August 15-17—**Sun Valley Emergency Medical Conference.** Sun Valley. Thursday-Saturday. Followed by a float trip on the Middle Fork of the Salmon River, August 18-20. Sponsors: Idaho Emergency Medical Services System; Idaho Chap, American College of Emergency Physicians; Idaho Chap, Emergency Nurses Assn; Idaho Committee on Trauma, American College of Surgeons; Rural Area Model System. Contact: Idaho EMS System, 450 W State St., Boise 83720. (208) 334-4245.

August 15-21—**Effective Diagnosis and Treatment of Infectious Diseases.** Middle Fork of the Salmon River, Idaho White Water Rafting. Thursday-Wednesday. 24 hrs. Cat. I. Sponsors: University of Arizona College of Medicine and Epic Medical Expeditions. Contact: Richard Paris, MD, PO Box 209, Sun Valley 83353. (208) 788-4995.

(Continued on Page 35)



"When it comes to cardiovascular medicine, I like to know exactly what my patients are swallowing."

There are doctors who say that generic drugs have a place in their practice—but not necessarily in the treatment of serious or potentially life-threatening disease. And when they consider that the average patient pays only about 45¢ a day for INDERAL (propranolol HCl) Tablets, there's not much left to discuss.

When it's INDERAL Tablets you want for the treatment of hypertension, angina, arrhythmias, or post-MI patients, make sure you specify "Dispense As Written" (DAW), "Do Not Substitute," or whatever is required in your State. That way, you'll know exactly what your patients will get.

Please see next page for brief summary of prescribing information.

INDERAL® Tablets

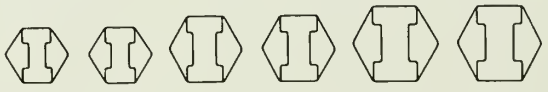
BRAND OF PROPRANOLOL HCl

Small price to pay.

"When it comes to cardiovascular medicine, I like to know exactly what my patients are swallowing."

INDERAL® Tablets

BRAND OF PROPRANOLOL HCl



10 mg 20 mg 40 mg 60 mg 80 mg 90 mg*

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

INDERAL® (propranolol hydrochloride) Tablets

CONTRAINDICATIONS

INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL

WARNINGS

CARDIAC FAILURE Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure Although beta blockers should be avoided in overt congestive heart failure, if necessary they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible)

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks and the patient should be cautioned against interruption or cessation of therapy without the physician's advice If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors

MAJOR SURGERY The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e g , dobutamine or isoproterenol However, such patients may be subject to protracted severe hypotension Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS Beta blockade may mask certain clinical signs of hyperthyroidism Therefore abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm Propranolol does not distort thyroid function tests

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker In one case this resulted after an initial dose of 5 mg propranolol

PRECAUTIONS

General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure Patients should be told that INDERAL (propranolol hydrochloride) may interfere with the glaucoma screening test Withdrawal may lead to a return of increased intraocular pressure

Clinical Laboratory Tests Elevated blood urea levels in patients with severe heart disease elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DRUG INTERACTIONS Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity There were no drug-related tumorigenic effects at any of the dosage levels Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug

Pregnancy Pregnancy Category C INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus

Nursing Mothers INDERAL is excreted in human milk Caution should be exercised when INDERAL is administered to a nursing woman

Pediatric Use Safety and effectiveness in children have not been established

ADVERSE REACTIONS

Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy

Cardiovascular bradycardia, congestive heart failure, intensification of AV block, hypotension, paresthesia of hands, thrombocytopenic purpura, arterial insufficiency, usually of the Raynaud type

Central Nervous System. Lightheadedness, mental depression manifested by insomnia, lassitude, weakness fatigue, reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal nausea, vomiting, epigastric distress, abdominal cramping, diarrhea constipation, mesenteric arterial thrombosis, ischemic colitis

Allergic pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory bronchospasm

Hematologic agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura

Auto-Immune In extremely rare instances, systemic lupus erythematosus has been reported

Miscellaneous alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

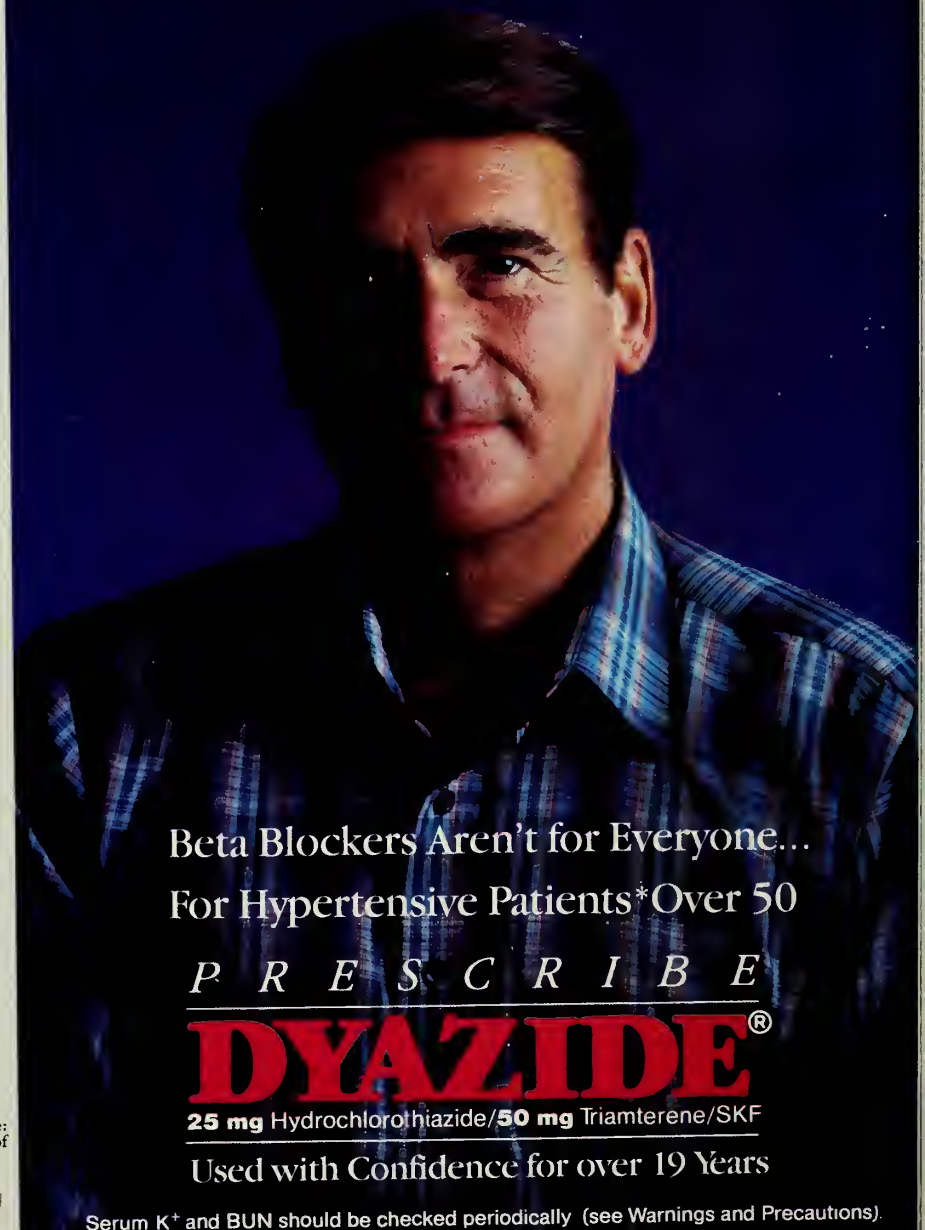
In Hypertensives Over 50, Diuretics Are Preferred

The 1984 Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure recommends diuretics as the favored monotherapy in patients over 50 years of age, regardless of sex or race.



Beta Blockers Aren't for Everyone...

For Hypertensive Patients*Over 50

P R E S C R I B E

DYAZIDE®

25 mg Hydrochlorothiazide/**50 mg** Triamterene/SKF

Used with Confidence for over 19 Years

Serum K^+ and BUN should be checked periodically (see Warnings and Precautions).

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: **Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired.** If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: The bioavailability of the hydrochlorothiazide component of 'Dyazide' is about 50% of the bioavailability of the single entity. Theoretically, a patient transferred from the single entities of Dyrenium (triamterene, SK&F CO.) and hydrochlorothiazide may show an increase in blood pressure or fluid retention. Similarly, it is also possible that the lesser hydrochlorothiazide bioavailability could lead to increased serum potassium levels. However, extensive clinical experience with 'Dyazide' suggests that these conditions have not been commonly observed in clinical practice. Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

Supplied: **'Dyazide' is supplied as a red and white capsule, in bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.**

Clinical Investigation

Epidemiologic and Clinical Factors of *Chlamydia trachomatis* in Black, Hispanic and White Female Adolescents

RONALD M. EAGAR, MD; ROBERTA K. BEACH, MD, MPH; ARTHUR J. DAVIDSON, MD, *and* FRANKLYN N. JUDSON, MD, *Denver*

Rates of genital infection with Chlamydia trachomatis, Neisseria gonorrhoeae *and* Trichomonas vaginalis *were determined prospectively in 396 sexually active female adolescents from three ethnically different urban teen clinics. The organisms were identified respectively in cultures of specimens from 21%, 7% and 6% of all adolescents; 28%, 16% and 20% of blacks; 23%, 4% and 2% of Hispanics, and 14%, 2% and 1% of whites.* C trachomatis *was identified in specimens from 27% of pregnant adolescents and from 42% of adolescents who had gonorrhea or trichomoniasis.*

Of 85 Chlamydia*-positive adolescents, 47 (55%) were asymptomatic. Physical findings significantly associated (*P < .001*) with chlamydial infection were vaginal discharge, cervical inflammation and mucopurulent endocervical discharge. Not significantly associated (*P > .05*) with* Chlamydia *were the use of oral contraception or symptoms of lower abdominal pain, vaginal discharge or dysuria. Because in sexually active female adolescents* C trachomatis *is three times more common than* N gonorrhoeae, *care givers need to consider routine screening or epidemiologic treatment (or both) for both pathogens.*

(Eagar RM, Beach RK, Davidson AJ, et al: Epidemiologic and clinical factors of *Chlamydia trachomatis* in black, Hispanic and white female adolescents [Clinical Investigation]. West J Med 1985 Jul; 143:37-41)

Chlamydia trachomatis has become the most common sexually transmitted pathogen of female adolescents.[1-3] Diseases associated with *Chlamydia* include cervicitis, salpingitis and its complications and the acute urethral syndrome in women; urethritis and epididymitis in men, and inclusion conjunctivitis and pneumonia in neonates.[4]

An estimated 10 million teenage women in the United States are sexually active.[5] Chlamydial infection rates of 8% to 26% have been reported for selected adolescent populations but vary considerably according to age, ethnicity, sexual activity, geography and other factors.[2,3,6-8] Unfortunately, most clinical correlates of infection have been unreliable, while laboratory cultures for *Chlamydia* are costly and not yet widely available; diagnosis is often presumptive. Finally, only limited information has been published on chlamydial infection rates in pregnant adolescents.[3,8]

We therefore undertook a study to (1) determine the prevalence rates of *C trachomatis, Neisseria gonorrhoeae* and *Trichomonas vaginalis* in pregnant and nonpregnant black, Hispanic and white female adolescents who attended one of three urban teen clinics, and (2) identify patient history or physical findings significantly associated with chlamydial infection.

Methods

Patients

Patients were sexually active female adolescents who received care at one of three Denver Department of Health and Hospitals adolescent clinics. The adolescent clinics at the Eastside Neighborhood Health Center (from which 148 of our patients came) and the Westside Neighborhood Health Center (149 patients) offer comprehensive primary care to

From the Disease Control Service (Drs Davidson and Judson) and the Neighborhood Health Program (Drs Eagar and Beach), Denver Department of Health and Hospitals, and the Departments of Pediatrics (Drs Eagar and Beach), Medicine, Division of Infectious Diseases (Dr Judson), and Preventive Medicine (Drs Davidson and Judson), University of Colorado Health Sciences Center, Denver. The Centers for Disease Control, Division of Sexually Transmitted Diseases, Atlanta, provided funding support for *Chlamydia* cultures.

predominantly low-income black and Hispanic young people. The Denver Free Teen Clinic (99 of our patients), located in the Denver Public Health Department, offers confidential services limited to contraception and pregnancy testing and serves primarily white teenagers from low- to middle-income families.

Any clinic patient who received a pelvic examination between October 1983 and March 1984 was screened for enrollment in this study. Women were included if they were 12 through 18 years of age, sexually active, had not taken any antibiotics or used any intravaginal preparation (spermicide, douche or suppository) within the previous 28 days and had not been a prior study participant.

Data Collection

To maintain consistency in collecting data, the study staff from the three clinics attended a joint training session on the study protocol and their work was continually monitored by one of the principal investigators. A standardized data entry form was used for the history and physical examination. Historical data included age, race, family income, reason for encounter, specific symptoms, contraceptive use, obstetric and gynecologic history, sexual history and previous episodes of sexually transmitted disease. Abdominal and pelvic examinations were carried out with special attention to vaginal discharge (profuse creamy or frothy discharge in vault), cervical inflammation (erythematous, eroded or friable cervix), mucopurulent discharge from the cervical os and pelvic tenderness. Endocervical cultures for *N gonorrhoeae* and *C trachomatis* and a vaginal wet mount for *T vaginalis* were done on specimens from all subjects.

Laboratory Techniques

Laboratory specimens were taken by the examining clinician using standardized techniques. Before the bimanual examination and after inserting a clean unlubricated speculum, specimens for *N gonorrhoeae* were obtained by inserting two consecutive cotton-tipped swabs in the endocervical canal, allowing 10 seconds for adsorption and inoculating the swabs 180 degrees apart onto a modified Martin-Lewis medium. Media were processed in the clinic's usual manner.[9] Presumptive identification of *N gonorrhoeae* consisted of typical colony morphology, a positive oxidase test and Gram-negative diplococci on a Gram's stain.

The specimen for *C trachomatis* was then collected by inserting a cotton-tipped swab into the endocervical canal with a vigorous rotary motion. Swabbed specimens were swirled and expressed into one-dram vials containing glass beads and 1 ml of transport media (0.2 mol per liter sucrose to 0.02 mol per liter phosphate, 4 μg per ml amphotericin B, 10 μg per ml gentamicin), which were immediately placed in an ice bath and transported the same day to the Disease Control Service Laboratory.* If specimens could not be inoculated into cells within 24 hours, they were stored at −70°C.

Cultures were done by vortexing the specimen and inoculating 0.2-ml aliquots into each of three one-dram glass vials containing a 12-mm coverslip coated with a confluent monolayer of McCoy cells (M.A. Bioproducts, Walkersville, Md). Vials were centrifuged at 3,000 g for one hour at 25°C to 35°C, the inoculum discarded, the monolayer rinsed once and 1 ml of medium added to each vial. Cultures were incubated for 48 to 72 hours at 30°C to 35°C. Coverslips were fixed in methanol, stained with iodine and examined for intracytoplasmic inclusions.

A cotton-tipped swab specimen of the posterior vaginal puddle was mixed with physiologic saline on a glass slide and viewed by light microscopy. Trichomoniasis was diagnosed by the presence of typical, motile, pear-shaped, flagellated protozoa.[10]

Statistical Methods

Quantitative analysis for possible risk factors was done using the χ^2 method.[11] Comparisons of rates of *C trachomatis* by race were done based on methods described by Rosner.[12] Because of the small numbers, Fisher's exact test was used to evaluate associations of *C trachomatis* and trichomoniasis.

Results

From October 1983 through March 1984, 396 female adolescents were enrolled in the study. The mean age was 16.2 years (range, 12 to 18). The principal reasons for clinic visits were the following: family planning, 192 (48%); genitourinary symptoms, 85 (21%): pregnancy diagnosis and pre-

Chlamydia cultures were prepared by Josephine Ehret.

TABLE 1.—*Obstetric and Gynecologic Characteristics of 396 Female Adolescents by Ethnic Group*

Characteristic	Ethnic Group							
	Black N=99		Hispanic N=166		White N=126		All N=396*	
Mean age (yr)	16.1		16.3		16.2		16.2	
Mean age menarche (yr)	12.4		12.2		12.5		12.4	
Mean age first intercourse (yr)	14.5		15.0		14.9		14.8

*Includes 2 Native American and 3 Southeast Asian girls.
†The percentages add up to more than 100 due to rounding off of numbers.
‡Includes pregnant women.
§Patients using spermicides were excluded from the study.

natal care, 80 (20%); postpartum care, 32 (8%); examination for sexually transmitted diseases, 9 (2%), and other, 10 (3%). Multiple reasons for visits were accepted. The study population included 99 (25%) blacks, 166 (42%) Hispanics, 126 (32%) whites and 5 (1%) others. Obstetric and gynecologic characteristics of the study population are given in Table 1. There were no significant differences by ethnic group except for a lower rate of pregnancy (7%) in white patients.

C trachomatis was identified in specimens from 21% (85/396) of all adolescent women (Table 2). The prevalence rate in black teenagers was twice as high as in whites (28% versus 14%, $P<.001$) and was significantly higher than in Hispanics (28% versus 23%, $P<.008$). Hispanics also had significantly higher rates than whites ($P<.001$). *N gonorrhoeae* was cultured in specimens from 7% (26/396) of all teenagers, but from 16% of blacks compared with 4% of Hispanics and 2% of whites. *T vaginalis* was seen in 6% of all women; 20 of 24 cases were in blacks, who had an infection rate of 20% compared with 2% in Hispanics and 1% in whites. Coexistent infection with *C trachomatis* was identified in 11 of 26 (42%) patients with gonorrhea and 10 of 24 (42%) with trichomoniasis. Nearly 27% (106/396) of all subjects had at least one of these three organisms.

A total of 86 (22%) patients were pregnant, of whom 23 (27%) had *Chlamydia*, 4 (5%) had gonorrhea and 7 (8%) had *T vaginalis*. When controlled for ethnicity, the rate of *Chlamydia* infection in pregnant teens was not significantly different ($P<.25$) from that in nonpregnant teens.

Of 85 patients with chlamydial infection, 38 (45%) presented with genitourinary symptoms (discharge, dysuria or abdominal pain). Symptoms reported after direct questioning and physical findings from pelvic examinations were compared with culture results (Table 3). No symptom, including the prevalent vaginal discharge, was significantly associated with a positive chlamydial culture. *C trachomatis* was identified in specimens from 38% of 113 women with the sign of vaginal discharge, 50% of 38 with cervical inflammation and 45% of 51 with mucopurulent endocervical discharge, each of which represents a significant association ($P<.001$). However, 30 of 85 (35%) did not have any of these three clinical indicators of infection. Pelvic tenderness on bimanual examination was not significantly associated with cultures positive for *Chlamydia* ($P<.9$).

Six patients had a clinical diagnosis of acute pelvic inflammatory disease at the initial visit. In one, culture was positive for *N gonorrhoeae*; in two, cultures were positive for *C trachomatis*, and three had negative cultures. The only patient diagnosed as having acute perihepatitis had a positive *Chlamydia* culture. No significant positive association was found between chlamydial infection and the use of oral contracep-

tives ($P < .25$), a history of gonococcal infection ($P < .95$), sexual contact within seven days ($P < .5$), chronologic age, age at first intercourse or years sexually active.

Discussion

The actual prevalence of *C trachomatis* in American teenagers is not known because true random sampling of large adolescent populations has not been done. Our study and others previously reported have focused on sexually active female adolescents, primarily from lower income families, who underwent pelvic examination at either comprehensive or gynecologic adolescent clinics. Even in these more limited populations, rates of *C trachomatis* infection have varied: 22% in Cincinnati,[6] 8% in Oklahoma City,[7] 15% in San Francisco,[2] 10% in Brooklyn[8] and 26% in Baltimore.[3] Our overall identification rate of 21% confirms that *C trachomatis* is a dominant pathogen in sexually active Denver urban teenagers.

Identification rates of both *C trachomatis* and *N gonorrhoeae* from black and Hispanic teens were higher than in previous studies of adolescents. Our sample of 166 Hispanic teens is the largest yet reported. *Chlamydia* infection was identified in 23%, compared with 14% found by Shafer and co-workers[2] and 6% by Golden and associates.[8] Likewise, the *Chlamydia* infection rate of 28% in black teens was higher than the 7% to 23% rates previously reported. Although minority teens are at significantly greater risk for *C trachomatis* infection than white teens, important confounding variables to race and ethnicity need further study. These may include geography, socioeconomic status, sexual activity patterns, the use of health care resources and laboratory techniques.

Pregnant indigent adolescents have been reported to have a high prevalence of *Chlamydia* infections,[3,13-15] which our rate of 27% confirms. If *C trachomatis* is untreated in the mother, Frommell and colleagues[13] found that perinatal transmission will occur in about 61% of neonates; inclusion conjunctivitis will develop in 73% and interstitial pneumonia in 18%. In addition, unconfirmed reports have associated maternal chlamydial infection with higher rates of spontaneous abortion, prematurity and postpartum endometritis.[14,15] Thus screening for *C trachomatis* would seem to be an important addition to routine prenatal care.

Because *Chlamydia* cultures are not widely available, investigators have attempted to identify symptoms or signs that might be reliable indicators of the presence of infection. Our study shows that no clinical symptom, including vaginal discharge, abdominal pain or dysuria, is reliably associated with chlamydial infection in female adolescents. Furthermore, 55% of our patients with *Chlamydia* infections were asymptomatic, similar to rates of 45% to 86% reported by others.[2,3,6-8]

We did find statistically significant ($P < .001$) associations between patients with chlamydial infection and the findings on genital examination of vaginal discharge, cervical inflammation and mucopurulent cervical dischage. Mucopurulent cervical dischage may be the most significant clinical marker of *C trachomatis*. Our finding *Chlamydia* in specimens from 23 of 51 patients (45%) with endocervical discharge is consistent with the recently published study of Brunham and co-workers,[16] who identified *C trachomatis* in specimens from 20 of 40 women (50%) who had mucopurulent cervicitis. They propose that mucopurulent cervicitis be diagnosed by the following more objective criteria: visualization of yellow mucopurulent endocervical secretions on a white swab or the presence of ten or more polymorphonuclear leukocytes per high power field (×1,000) in a satisfactory Gram-stained smear. In most published studies of adolescents, owever,including this report, cervical abnormalities have been either unmentioned or variously reported as inflammation, rosion, ectopy or friability, so that comparison of findings is not possible. Future studies need uniform criteria for describing cervical findings.

Presumptive treatment of all adolescents with any one of the significantly associated physical markers of chlamydial infection—that is, vaginal discharge, cervical inflammation or mucopurulent cervical discharge (or all of these)—would result in the correct treatment of 50 of 85 (59%) infected patients and the unnecessary treatment of 108 of 311 (35%) uninfected patients. Whether or not this approach would be viewed as a cost-effective control effort or inappropriate treatment is a value judgment.

The frequent coexistence of *N gonorrhoeae* and *C trachomatis* infection has been well enough documented[17-19] that the Centers for Disease Control now recommend that patients with *N gonorrhoeae* be treated with a regimen that is also effective against *Chlamydia*.[20] Our finding that 42% of patients with gonorrhea also had cultures positive for *Chlamydia* supports this recommendation. *T vaginalis* is an easily diagnosed sexually transmitted organism that can serve as a marker of sexual activity.[10] It was found in 6% of our subjects, of whom 42% also had cultures positive for *Chlamydia* ($P = .006$), a finding that is comparable to the study of Shafer and colleagues[2] in which 32% of subjects with trichomonads on Papanicolaou smears had cultures positive for *Chlamydia* ($P = .009$). This relationship needs further investigation but suggests that teenaged girls with trichomoniasis should either be screened for *Chlamydia* or receive presumptive treatment.

Implications

This large study confirms that *C trachomatis* is the most common sexually transmitted pathogen in sexually active urban adolescents. American teenagers with chlamydial infections have not been studied longitudinally to determine morbidity, but the many possible complications raise serious concern. In Scandinavian studies, *C trachomatis* has been associated with 40% to 60% of laparoscopically proved salpingitis.[21] Westrom estimates that in the 15- to 24-year-old age group, 9.4% will become infertile after one episode of salpingitis and 51.6% after the third episode.[22] In his studies, estimates of the risk for ectopic pregnancy escalate from 1 in 300 without salpingitis to 1 in 24 following salpingitis. *Chlamydia* may well play some etiologic role in the tripled incidence of both infertility and ectopic pregnancy reported in the United States during the past decade.[16,21,23] These sequelae, along with the immediate morbidity associated with the enlarging spectrum of chlamydial diseases in patients, partners and offspring, represent a major public health concern reminiscent of gonorrhea in the late 1960s and early 1970s. The methods used to control *N gonorrhoeae*—widespread routine culturing, reporting to public agencies, aggressive treatment of contacts—should be considered for *Chlamydia*.

At present, a culture is the only reliable means of diagnosing *C trachomatis*, but cultures are expensive, labor intensive, require 72 hours for results and are not widely available. Screening tests based on antigen detection systems are promising but require further study.[24]

Until more adequate diagnostic tests for *Chlamydia* are available, we suggest the following guidelines to care givers of sexually active adolescents:

- For diseases consistently and significantly associated with chlamydial infection (mucopurulent cervicitis, gonorrhea, salpingitis and distal urethritis in women; gonococcal and nongonococcal urethritis and epididymitis in men), treat with an antimicrobial regimen that includes treatment for *C trachomatis*.
- In women with trichomoniasis or vaginal discharge of any cause, maintain a high index of suspicion for chlamydial infection and consider using treatment effective against *C trachomatis*.
- If chlamydial cultures are available, take specimens for culture from any sexually active teenaged girl (particularly if pregnant) who would not otherwise receive treatment for *Chlamydia* on the basis of risk factors of infection noted above.
- Simultaneously treat partners of patients with known or suspected chlamydial infection with effective treatment.
- Educate adolescents about the risks and sequelae of sexually transmitted diseases, including the seldom-heard-of *Chlamydia* infections.

Current Concepts in Endometriosis

CRAIG A. MOLGAARD, PhD, MPH; AMANDA L. GOLBECK, PhD, *and* LOUISE GRESHAM, MPH, *San Diego*

There are no conclusive data available on the incidence or prevalence of endometriosis, yet the notion persists that the frequency of cases has dramatically risen in western societies during the past 25 years. Race, familial predisposition, reproductive history, socioeconomic status, personality type and a historical drop in age at menarche have been posited as risk factors for the complex and as-yet-unclear epidemiology of this disorder.

The epidemiology of endometriosis is constrained by the difficulty of the diagnosis. Several analytic concepts from epidemiology, however, could be profitably used to further our knowledge of endometriosis. Included are the case-control study, survival and life-table analyses and correlations of psychologic traits with susceptibility to development of the disease. Though none of these techniques is original or without potential for bias, they may be underutilized in solving the conundrum of endometriosis.

(Molgaard CA, Golbeck AL, Gresham L: Current concepts in endometriosis. West J Med 1985 Jul; 143:42-46)

Endometriosis is a crippling and enigmatic disorder that frequently coexists with severe pelvic pain and infertility. It is characterized by the presence of tissue resembling endometrium, the mucous membrane lining the uterus, in various abnormal locations including the uterine walls, ovaries or extragenital sites. Endometriosis was first brought to the attention of the medical community by Rokitansky in 1860. Between that time and Sampson's contributions to knowledge of this disease in the 1920s, fewer than 20 cases of endometriosis were reported in the literature.[1] Thereafter, reported cases have dramatically increased in western societies. The onset of endometriosis during the reproductive years may prevent childbearing and often necessitates a hysterectomy or castration. The exact cause of infertility in patients with this disease—twice the rate of that found in the normal population—is not known.

The epidemiology of endometriosis is not well defined. The purpose of this review is to provide a summary of current concepts contributing to our population-level knowledge of this disease and to promote future analyses using epidemiologic tools in the study of endometriosis.

Salient Clinical Features

Etiology

The pathogenesis of endometriosis is unclear. The most popular notion is that it is caused by implantation of endometrial cells, although why endometrial cells should be implanted at abnormal sites is a mystery. Marik[2] has reviewed the numerous theories of etiology and made the point that no one theory explains the presence of endometriosis in all of the unusual locations where it has been found. He categorized the causative theories into three main groupings: transport, mutation and a combination of these. Transport could occur by spontaneous implantation, surgical or iatrogenic transplantation, metastasis via lymphatic channels or blood vessels or by direct extension to organs immediately adjacent to the uterus. Mutation could result from coelomic metaplasia, ovarian metaplasia, dedifferentiation or from activation of embryonic rests by the cyclic female hormonal stimuli to form aberrant endometrial tissue.

A recent genetic study indicated multifactorial inheritance: 7% of first-degree relatives of the index cases were affected compared with 1% of a control group consisting of relatives of the patients' husbands.[3] This control group was chosen because they were considered similar to the general population in terms of life-style, socioeconomic status, professional goals and age. A tendency for familial aggregation of cases has long been noted, though the inherited endocrinologic, enzymatic or chemical mechanisms are unknown. None of these causes is more powerful than the others in explaining the posited association with infertility.

Symptoms

Endometriosis may be acute or chronic and the site of the disorder often affects the type and degree of symptoms. Although endometriosis occurs most frequently in the pelvic region, on rare occasions it has been located in such distant sites as the gallbladder, kidneys, spleen, lungs and skin. The four cardinal features of the disease are infertility, dysmenorrhea and pelvic pain, dyspareunia and menstrual problems.[4] Differential diagnoses include adenomyosis, pelvic inflammatory disease, nonspecific adhesions and ovarian carcinoma.[5]

Patients with massive endometriosis may be devoid of symptoms, whereas a woman with only minor endometriotic involvement may be incapacitated with dysmenorrhea or pelvic pain. Pelvic pain may be due to direct action of endometriosis on local nerve endings or to impaired function of involved or adjacent organs. In either case, a definitive diagnosis of endometriosis cannot be made without direct visualization, either by laparotomy or laparoscopy.[6] Determining the incidence and prevalence of endometriosis has been severely constrained in the past by the difficulty of the diagnosis.

Treatment

Choice of treatment depends on the situation of an individual patient. The three major options are organ excision, conservative surgical treatment or medical treatment.[7] Organ excision involves removing the internal pelvic reproductive organs, that is, the source of the endometriosis (the uterus) and the hormonal stimulus for its growth (the ovarian hormones), by a hysterectomy and bilateral salpingo-oophorectomy. Conservative surgical removal consists of excising tissues with endometriosis. Medical treatment attempts to end menstruation through the use of oral contraceptives, progestogens (to cause pseudopregnancy) or danazol (to cause pseudomenopause). A recent study by Shaw[8] points to intranasal treatment with buserelin acetate, an analog of natural luteinizing hormone-releasing hormone, which blocks release of pituitary gonadotropins, in turn suppressing ovarian steroid production. Comparison of treatment alternatives is extremely difficult because of the lack of isomorphism between symptoms and degree of involvement; the tendency of endometriosis to regress, especially if pregnancy occurs, and the lack of a universally accepted classification system for endometriosis. The last affects not only the comparison of studies of treatment efficacy, but also the interpretation of frequency of occurrence estimates by different researchers.

Recurrence of endometriosis is variable and depends on the type of intervention involved. It cannot be predicted by the severity of the endometriosis.[9]

Epidemiologic Features

Information concerning the prevalence of endometriosis is incomplete, though pelvic endometriosis has been reported in 5% to 15% of all women having pelvic operations.[10] Corson[11] has suggested that it occurs less in England and Australia than in the United States. However, the notion persists that the incidence is increasing,[12] supported by increased case findings in recent decades. Concomitantly, a constellation of epidemiologic beliefs has evolved concerning endometriosis, the most general of which is that endometriosis is a product of modern civilization. This theory is based on the supposed infrequency of endometriosis among blacks and Asians.[13-15]

A second notion is that of an endometriosis personality type, Kistner[16] describing this as the interaction of body type and psychic demeanor. The main characteristics involve being mesomorphic but underweight, having above-average intelligence, a higher than normal anxiety level, egocentrism and a need for perfection.

Age at diagnosis, in lieu of age at onset, is usually the third or fourth decade. Absence of the condition in girls before menarche is explained by the fact that endometriosis requires fluctuating levels of estrogen and progesterone for its initiation and spread. Endometriosis, however, may be symptomatic after menopause if there is a resurgence of endogenous hormonal stimulation or if the use of exogenous hormones stimulates the endometriosis.[17]

In terms of reproductive history, the condition is believed to be more common in women who delay their first pregnancy and less common in the highly parous.[18] The lack of opportunity for retrograde menstruation among the latter group has been offered as a possible explanation.

Related to reproductive history is the usually higher-than-average socioeconomic status of women with this condition. Women from high socioeconomic groups tend to have fewer and later pregnancies than those from lower socioeconomic groups.[19] The position has been taken that the incidence is lower in blacks not because of race, but because of endemic poverty among a large proportion of the black population.[20] Poverty could create an apparent differential in disease occurrence among racial groups because of differential access to specialized medical care and the existence of a prejudicial diagnostic posture based on what is "known" about racial susceptibility to endometriosis.

Association With Infertility: Spurious or Real?

Support for the association between endometriosis and infertility is based on clinical data and has been well accepted. The argument has been based on the assumption that infertility characterizes 15% of the general female population of reproductive age, and that this increases to 30% to 40% in the population of patients with endometriosis.[5] Further support for the association involves surgical series, where subsequent pregnancy rates of 40% to 73% occurred among patients with endometriosis (and no other cause for infertility) following conservative surgical treatment.[21]

It is possible, however, that the apparent relationship between infertility and endometriosis is an example of sampling bias related to the frequency with which a laparotomy or laparoscopic examination is used to evaluate cases of infertility. Few studies have reported if laparoscopy was done as a routine procedure in the evaluation of infertile patients when physical examination had shown no other positive findings, or what signs and symptoms are considered sufficient to warrant laparoscopy. Information supporting the association of endometriosis and infertility has been considered inconclusive.[22]

Given that the association exists, it has been held in the past that endometriosis does not cause infertility unless it is severe enough to alter tubo-ovarian function. If both tubes and ovaries are involved in the process and peritubal adhesions are present, tubal dysfunction could impair ovum pickup. The increased use, however, of laparoscopy in infertility studies

has revealed the coexistence of minimal endometriosis (peritoneal involvement only) and infertility. It is unclear how the mild form of endometriosis can alter the process of conception, and this fact has led to the suggestion that minimal endometriosis may be the effect rather than the cause of infertility.[23] Yet evidence for the efficacy of conservative surgical treatment in cases of even mild endometriosis has continued to accumulate. Buttram[21] evaluated the effect of conservative operations on 56 patients with mild endometriosis as the only known cause of infertility: 78% of these women had been trying to conceive for two or more years. Within 15 months after an operation, 73% were pregnant. His cautious conclusion was that the surgical procedure somehow altered the pelvic environment (enzymatic, chemical, immunologic) so that the effect of the endometriosis on fertility was altered. In contrast, a subsequent study[24] based on a life-table analysis of conceptions concluded that mild endometriosis does not necessarily interfere with fertility.

One current theory explaining the relationship between endometriosis and infertility is immunologic. It proposes that ectopic or abnormal endometrium is recognized differently by the immune system, which launches an antibody response to the condition that may affect the patient's fertility. An autoimmune response is triggered in some women when endometriotic tissue is phagocytized and absorbed by the host. This might cause rejection of an embryo or disrupt sperm transport.[25] A second theory posits that the ovum may be attracted to any endometrium wherever it is located. Evidence for this position involves reports of abdominal pregnancies in areas of endometriosis. Given that the distance between the ovary and normal endometrium is greater than that between the ovary and the endometriosis, a patient's fertility could again be impaired. A third theory, which is the subject of controversy, is that of the "luteinized unruptured follicle" syndrome.[26] In brief, this hypothesis posits a situation wherein the ovarian follicle fails to release the ovum despite proceeding through the other changes associated with ovulation. This assumes that retrograde menstruation is actually a common event, that endometrial cells do not implant as frequently as they might and that the failure to implant can be explained by steroid hormone concentrations in peritoneal fluid. Women with complete ovulatory cycles have very high steroid hormone (progesterone) concentrations after ovulation, which would prevent growth and development of endometrial cells by rendering them inactive, whereas women with unruptured luteinized follicle syndrome do not.[25] The result would be infertility and endometriosis, but infertility would be the cause of endometriosis, as mediated through the unruptured luteinized follicle syndrome, and not the result. This hypothesis has been challenged as being very inaccurate.[27] The most general criticism has been that identifying the stigma, or site of the ovum release, by laparoscopic examination of the surface of the luteal structure is fraught with potential for error. If the stigma is absent, luteinized unruptured follicle is presumed, but recognizing the stigma depends on the experience of the laparoscopist, the time in the cycle and other idiosyncratic factors. This compromises any examination of the frequency of stigmata in relation to the varying severity of endometriosis.

A fourth theoretical position[28] claims no causal relationship to date involving the role of prostanoids in the peritoneal cavity and infertility among endometriosis patients. A fifth theory points to the high concentrations of peritoneal macrophages found in patients with this disease. Attracted perhaps by irritants in the oviduct, monocytes migrate to the peritoneal region and differentiate into macrophages, possibly resulting in sperm phagocytosis.

Of the major epidemiologic research designs, a case-control design is perhaps the only appropriate choice for the study of the association between endometriosis and infertility. A case-control study was recently undertaken at the Mayo Clinic to compare the presence of endometriosis in infertile and fertile populations as visualized by laparoscopy.[29] The medical records retrieval system of the Rochester Epidemiology Program Project was used to conduct the study.[30] The records of 100 Mayo Clinic referral patients who had been evaluated for infertility by means of laparoscopy between 1970 and 1979 were retrieved. Operative reports were reviewed for each case and the extent of endometriosis or adhesions or both were classified according to a system proposed by the American Fertility Society.[31] This classification system is a four-stage model (mild, moderate, severe and extensive) based on the site, size and type of endometrial involvement. Of the cases, 12% had a clinical diagnosis of endometriosis before the index date.

From 1,905 patients who had laparoscopy for tubal ligation during the same time period, 200 fertile controls were chosen. Controls were matched to the cases by age (± 2 years) at the time of laparoscopy and by clinic registration numbers so that the length of time of medical care in the Mayo system was similar. The approach of comparing fertile and infertile populations for endometriosis as documented by laparoscopy was considered to be superior to previous reports relating endometriosis and infertility based on data describing conception after treatment of endometriosis. However, several caveats must be inserted. Both cases and controls were taken from the clinic referral series, and a bias in the choice of patients certainly exists. A population-based case-control study was not deemed feasible given the relatively small population of Rochester, Minnesota. Second, by the nature of the design, the comparison is extreme.

Of the infertile patients, 21/100 (21%) were found to have endometriosis, including 11 mild, 8 moderate and 2 severe cases. Among the 200 fertile controls, only 4 (2%) had evidence of endometriosis, all staged as mild. Thus, endometriosis is significantly more common ($\chi^2_1 = 31.52$, $P < .001$) and, when present, more severe in infertile as compared with fertile patient populations. These findings serve to confirm the clinical impression that an association between endometriosis and infertility exists, but casts little light on the direction of the causation. A question regarding this study is whether the fertile control population was capable of pregnancy because of the absence of endometriosis or whether there was an absence of endometriosis because of past pregnancies. One can look at two types of information to try and answer this question: the type of infertility present in patients with endometriosis and the relative frequency distributions of obstetric history before a laparoscopy.

In the Mayo study 16 of 21 patients (76%) had primary infertility, which is in close accord with Buttram's[21] work, in which 71% of 206 infertility patients had primary endometriosis. One could argue that when endometriosis is present, it is

more likely that the patient has never been pregnant. However, Kistner[32] has suggested that infertile women, particularly those with endometriosis, have more fetal losses than do normal women. Data from the Mayo study do not support this: infertile nonendometriosis cases showed a rate of fetal loss three times that of infertile endometriosis cases; both infertile groups combined indicated less fetal loss than normal controls (21% to 24%). Although speculative, it would seem that a tendency does exist for patients with endometriosis never to have been pregnant (Table 1). The prevalence of endometriosis in this study (21%) agrees in general with other reports of the frequency of endometriosis diagnosed by laparoscopy in populations treated primarily for infertility rather than for pain or mass (5% to 30%).[11] Also, the distribution of endometriosis in this case-control study was skewed to less severe or extensive involvement (stages 1 and 2).

Demographic Considerations

At least part of the suggested increase in the incidence of endometriosis can be attributed to the relative availability of laparoscopy for the diagnosis of pelvic conditions in recent years. This can also account for the comparatively low occurrence in certain racial and socioeconomic groups, with the less affluent being constrained in their access to and utilization of medical resources for the complete investigation of pain or infertility or both.

Another portion of the suggested increase in endometriosis can be attributed to changes in the demographic pattern of fertility in some western nations during the past few decades. Specifically, given that pregnancy protects against endometriosis, a pattern of lower parity and delayed pregnancy could result in increased occurrence of the disease. The national trend to delay childbearing is reflected in a reported 37% increase between 1975 and 1979 in the number of women in the United States who had their first child between ages 30 and 35 years.[33] In general, as ages at first marriage and first birth increase, rapid fertility decreases as measured by the proportion having a birth within a given period after marriage or a preceding birth.[34,35] In turn, there is a tendency for women with a long first-birth interval to have a long second-birth interval as well.[36] Coupled with the limited reproductive span and the widespread availability of organized family planning programs, these factors have served to lower the parity profile in many western countries. For a parity-related disease, such as endometriosis, these factors could induce an increase in incidence through time by increasing the period when women of reproductive age are at risk.

A second major fertility variable that could affect the occurrence of endometriosis is a change in the age at menarche. Of the various factors that may account for rising preteen and early teen sexuality, pregnancy and fertility, one of the most commonly cited is a drop in the age of menarche. Specifically, the average age at menarche for United States resident women was thought to have dropped from 17 years in the 19th century to 12.5 years today.[37] If the proposed drop in age at menarche is true, the length of the reproductive span would increase. Given the nature of endometriosis, this could result in an increased occurrence. However, Bullough[38] has argued that while there has been some drop in the age at menarche in the United States over the past century, it has been less than assumed, with the 17-year average age at menarche for the 19th century being a misinterpretation of historical data. The more accurate age for the 19th century is estimated to be between 12 and 14 years, although some sources continue to set a later date.[5] If Bullough's interpretation is followed, the drop in average age at menarche for the United States populations over the past century has been, at most, less than two years. Spread over a century, it is unlikely that such a drop could account for any real increase in the frequency of endometriosis.

Summary and Recommendations

At least three factors could contribute to a purported rise in endometriosis. The first is the increased use of laparoscopy as a diagnostic technique during the past few decades. The real incidence of the disease would not be increasing, but more of it is being found. The second and third factors, lower parity and delayed pregnancy, could be causing an actual increase in disease occurrence.

There is a clinical consensus on the association of endometriosis and infertility, but little consensus on the direction of the causation or on the etiology of endometriosis itself. The epidemiology of endometriosis is severely limited by the difficulty of the diagnosis, and this is unlikely to improve substantially. It is necessary to use surgical incidence studies as the main source of epidemiologic data, and such records have inherent limitations of referral and sample selection bias.

Three epidemiologic tools could be used to further our knowledge of endometriosis. Additional case-control studies could be carried out in other medical institutions to further evaluate the association with infertility. Because the Mayo Clinic study population was 99% white, case-control studies based on other racial groups and socioeconomic strata would be of comparative value. The notion of an endometriosis personality type should be further investigated. Although establishing correlations of psychologic traits with susceptibility to the development of disease is difficult, if recurring patterns have been observed by clinicians, they should be documented

by appropriate sociologic, physical and psychological measures. A pilot questionnaire to clinicians working with endometriosis patients would be a simple first step. Third, life-table analysis could be carried out in a prospective manner on the results of the therapy for infertility among endometriosis patients. A notable application of the life-table method to the study of endometriosis is the report by Adamson and co-workers.[39] If coupled with a relatively homogeneous patient population and the classification system for endometriosis of the American Fertility Society, such a method of presenting treatment results would aid in the comparative evaluation of regimens and allow patient and physician to evaluate together the statistical childbearing expectancies of various therapies. It might also lend itself to evaluating biologically plausible explanations for the conundrum of mild endometriosis and infertility.

Intestinal Parasites in Southeast Asian Refugee Children

RUTH ANN PARISH, MD, *Seattle*

To determine the predictability of pediatric stool-parasite patterns among various Southeast Asian ethnic groups, I collected data from medical and microbiology laboratory records on all Southeast Asian refugee children who had a stool specimen examined for ova and parasites over a 21-month period. For most of the children, the specimen was examined as part of routine "health screening." The patterns of infection by ethnic group for those Vietnamese and Laotian children living in Seattle differ from the patterns seen in other geographic areas.

(Parish RA: Intestinal parasites in Southeast Asian refugee children. West J Med 1985 Jul; 143:47-49)

Of the many studies in which the infection rates and varieties of intestinal parasites in Southeast Asian refugees now living in the United States have been examined, only two focused specifically on children.[1,2] In the study by Tittle and co-workers, 65 out of 100 Southeast Asian pediatric patients had one or more intestinal parasites present on initial screening ova and parasite examination.[2] These authors also suggested that different patterns of stool parasites occur among different ethnic groups within the Southeast Asian pediatric refugee population.

I did a retrospective study to examine a larger series of Southeast Asian children with intestinal parasites and to determine whether the notion of discrete stool-parasite patterns among various ethnic groups is valid in the Seattle area.

Patients and Methods

Data were collected from the medical records and Microbiology Laboratory records of all Southeast Asian children whose stool specimens were examined for ova and parasites between March 1, 1981, and December 31, 1982, a time of maximum refugee influx to the Seattle area. All had been in the United States for fewer than 18 months at the time of initial visit and presented to the Harborview Medical Center Pediatric Clinic for initial health screening and ongoing well-child care. Stool specimens were examined for ova and parasites as part of well-child care and health screening in 75% of the children, who were asymptomatic; in the remaining 25%, the stool specimens were examined for ova and parasites as part of an evaluation for abdominal pain, diarrhea or failure to thrive (or all of these).

Stool specimens were examined for parasites by one of three laboratory technicians in the Microbiology Laboratory at Harborview Medical Center. Fresh specimens were preserved in polyvinyl alcohol and 10% formaldehyde solution at a ratio of approximately one part stool to four parts preservative; these were processed by direct-formaldehyde solution-ether concentration of formalinized material and Wheatley trichrome stain of polyvinyl alcohol material.[3]

Results

The total number of stool ova and parasite specimens submitted from Southeast Asian children seen in Pediatric Clinic during the 21-month period was 461. Of these 461 specimens, 338 represented a child's first specimen examined, and these 338 children became the study population. Of those patients, 184 were Laotian (lowland), 5 were Lao-Mien, 14 were Hmong, 102 were Khmer (Cambodian) and 33 were Vietnamese. Ages ranged from 5 weeks to 16 years, with a mean age of 6.5 years. There were no significant differences in age distribution, sex or time of US arrival among the ethnic groups.

Table 1 lists the number of positive identifications and the distribution of multiple infections among the 338 patients. Roughly half of those examined had one or more parasites identified (positivity rate, 55.6%), and of those with positive findings, half had multiple species identified. In our sample, no child younger than 6 months had an intestinal parasite found in a stool specimen.

Table 2 shows the number of children in each ethnic group with one or more positive identification(s) and the total number of parasite species positively identified for all children in that ethnic cohort. The Laotian children appear to

have a slightly higher average number of different parasites per infected child than other ethnic groups. The cohorts differed significantly in their positivity rates ($\chi^2=19.61$, degrees of freedom [df]=4, $P<.001$). Partitioning of the groups[4] indicated that Laotians and Cambodians as a group had significantly greater positivity rates than did the Lao-Mien, Hmong and Vietnamese as a group.

Table 3 gives the positive identifications by species of parasite and the ethnic origin of the children. The parasite species are arranged in decreasing frequency of identification for the whole sample. The first three species (*Giardia lamblia*, hookworm and *Clonorchis sinensis*) accounted for 56.2% of all positive identifications. *G lamblia*, *C sinensis*, *Trichuris trichiura* and *Hymenolepis nana* all showed significant differences in infection rates across the three ethnic groups that resulted when the Lao-Mien and Hmong children were combined into a single cohort with the lowland Laotian children.

TABLE 1.—*Children in Sample (N=338) With Single and Multiple Parasites Identified in Stool**

Parasites	Children With Pos. Specimen — Number	Parasites Identified — Number	
Single	94	(×1)	94
2	57	(×2)	114
3	22	(×3)	66
4	13	(×4)	52
5	1	(×5)	5
6	1	(×6)	6
Total	188		337

*Overall positivity rate=55.6 per 100 specimens.

Discussion

The positivity rate for parasite infection found by examining a single stool specimen in this pediatric population (55.6%) is comparable to the rate seen in adult populations

TABLE 2.—*Children Tested and Positive Identifications by Ethnic Group**

Ethnic Group	Children Tested — Number	Children With Pos. Stools for Parasites — Number	Organisms Identified — Number	Parasites per Infected Child — Mean	Positivity Rate† — Percent

studied.[5-11] *G lamblia* and hookworm are the most frequently encountered of the intestinal parasites in our Southeast Asian pediatric population, followed closely by *Clonorchis, Strongyloides stercoralis* and *Endolimax nana.* No clear predominance of nematodes, cestodes, trematodes or protozoa appeared in this population.

Our patterns of organism prevalence by ethnic origin differ from those found in other pediatric studies, which also reported findings on a single stool specimen. Goldsmith and associates found *Giardia, Ascaris* and *Entamoeba histolytica* the most common intestinal parasites among Vietnamese infants in San Francisco,[1] although this study looked only at children younger than 1 year. In our Vietnamese group, hookworm and *Trichuris* were most common. Tittle and colleagues found that Laotian children, ages 2 weeks to 17 years (N=36) had hookworm and *Trichuris,*[2] whereas in our sample *Giardia* and *Clonorchis* were most frequent. (In fact, 94% of all *Clonorchis* found was identified among lowland Laotians.) Cambodian children in Tittle's and our study had predominantly hookworm, *Giardia* and *Strongyloides.* The number of children in our sample from the smaller ethnic groups (Lao-Mien, 5; Hmong, 15) was too small to evaluate statistical significance.

Other studies looking at various Indochinese refugee populations of all ages have indicated that people of different ethnic origins will have different intestinal parasites.[12-15] However, most of the reports on Southeast Asian refugees have not separated ethnic groups, but have "lumped" all Southeast Asian refugees together.[5-11]

Of the intestinal parasites found in our pediatric population, *Entamoeba coli, Endolimax nana, Iodamoeba bütschlii* and *Entamoeba hartmanni* are considered nonpathogenic and do not need treatment. Effective therapies are available for the other parasitic infections, however, as has recently been reported in an excellent review.[16]

Summary

The patterns of parasite infection by ethnic group in the Seattle child-refugee population may not be identical with those found elsewhere. Routine screening of asymptomatic patients in pediatric refugee populations for the presence of intestinal parasites appears to be warranted in the Seattle area.

Nonoperative Management of Acute Idiopathic Colonic Pseudo-Obstruction (Ogilvie's Syndrome)

CRAIG S. FAUSEL, MD, *and* JOHN S. GOFF, MD, *Denver*

In a four-year experience (35 episodes in 27 patients) with the use of medical and colonoscopic therapy for acute idiopathic colonic pseudo-obstruction, we have found that initial conservative measures followed by flexible colonoscopy in nonresponders are effective and safe. Contrary to previous reports, an initial nonoperative approach including colonoscopy is frequently successful and the outcome with this approach is not adversely affected even in the few patients who eventually require surgical decompression.

(Fausel CS, Goff JS: Nonoperative management of acute idiopathic colonic pseudo-obstruction [Ogilvie's syndrome]. West J Med 1985 Jul; 143:50-54)

Acute colonic pseudo-obstruction, first described in 1948 by Ogilvie,[1] is a nonmechanical dilatation of the colon often associated with severe illness or injury. Synonyms for the condition include Ogilvie's syndrome, colonic ileus, large intestinal colic and idiopathic large bowel obstruction. The dilatation involves the cecum and varying lengths of more distal colon. Often a "cutoff" of distention can be identified at the hepatic, splenic or sigmoid flexures. Cecal distention may become extreme (up to 20 cm or more) and result in perforation.

Because patients with acute colonic pseudo-obstruction usually are very ill, noninvasive treatment often is attempted in hopes of avoiding surgical intervention. However, cecal perforation is an understandably feared risk of such a conservative approach, so there are many proponents of emergency operation. This dilemma is intensified by inconsistencies in indications given for operation. There is no agreement on the maximal permissible distention of the cecum, and some[2-4] have advocated doing a surgical procedure immediately, whereas others[5,6] prefer a trial of conservative therapy first. In addition, it is important to differentiate true colonic obstruction from pseudo-obstruction although guidelines for surgical intervention in cases of true obstruction are also not well defined. A water-soluble contrast barium enema is probably the quickest and safest way to distinguish between true obstruction and pseudo-obstruction, though this can also be accomplished with colonoscopy.

As an alternative to operative decompression, Kukora and Dent[7] used colonoscopy with a flexible instrument. Since that small series (five patients) was reported in 1977, other reports have appeared, but only two are larger.[8,9]

In an effort to more precisely define the clinical course of acute colonic pseudo-obstruction and the response to and indications for various kinds of therapy (colonoscopic decompression in particular), we have reviewed our experience of four years.

Patients and Methods

We have reviewed the courses of all patients referred to the Gastroenterology Service with possible acute colonic pseudo-obstruction and those of all other patients with that diagnosis in our institutions (University of Colorado Hospital and Denver Veterans Administration Medical Center [VAMC] from January 1, 1979, through December 31, 1982. Acute colonic pseudo-obstruction was diagnosed if the cecum was acutely dilated to more than 9 cm with or without varying degrees of small bowel dilatation on plain roentgenograms of the abdomen. Cases of true mechanical obstruction (luminal compromise by intrinsic lesions or by extrinsic compression) or toxic megacolon (colonic dilatation due to inflammatory disease) were excluded in all patients either by colonoscopic examination, contrast radiography or by clinical presentation and subsequent course. No patients had the syndrome of chronic idiopathic intestinal pseudo-obstruction.

Retrospectively, three levels of treatment were defined: level 1—nasogastric suction, rectal tube, enemas, correcting electrolyte disturbances and withdrawing narcotic therapy; level 2—level 1 plus colonoscopic decompression; level 3—operative decompression.

All patients were treated with some level 1 modalities (see Table 1) for varying periods of time before referral to the Gastroenterology Service. Patients in whom the cecal diam-

*Same patient with recurrence.

eter equaled or exceeded 12 cm despite level 1 measures were deemed treatment failures and immediately had colonoscopic decompression with an Olympus TCF-2L flexible colonoscope. No specific bowel preparation preceded the procedure. An attempt was made to insufflate the smallest amount of air possible to visualize the lumen in the distal colon. When the ascending colon was reached, the colonoscope was slowly withdrawn while keeping the scope in the center of the lumen and using suction to remove the air and fluid contents. Colonoscopic success was defined as a decrease in the abdominal distention and a decrease in cecal diameter of more than 3 cm, as documented by a postprocedure plain roentgenogram of the abdomen. Eight cases (patients 1 to 8 in Table 1) were not referred to the Gastroenterology Service but were found by chart review. Review of these cases was felt to be important so as to better assess the natural history of conservatively treated acute colonic pseudo-obstruction uninterrupted by colonoscopic intervention at a predetermined cecal diameter.

Results

Patient Profile

There were 27 patients—20 men and 7 women—with 35 individual episodes of acute colonic pseudo-obstruction. The male predominance probably reflects the fact that most of the patients were seen at the Denver VAMC. Patients' ages ranged from 23 to 80 years (mean, 61 years). All patients had severe associated illnesses including cancer (nine), metabolic abnormalities (seven), respiratory failure requiring mechanical ventilation (seven), nongastrointestinal infections (eight), fractures (six) and drug toxicity (four).

Symptoms, Signs and Laboratory Tests

The most common presenting symptom of acute colonic pseudo-obstruction was abdominal distention. The rapidity of onset of distention was variable, but no patient had a fulminant course (a few hours from onset to perforation) or perforation unaccompanied by recognized distention. Most patients had mild to moderate discomfort, but a few complained of more severe, crampy abdominal pain; most had constipation, although a small number presented initially with watery stools and continued to pass small amounts of flatus. Some patients had nausea but none vomited.

Physical examination in all cases showed massive abdominal distention. Usually there was mild to moderate tenderness and peritoneal signs were rare in uncomplicated cases; in one patient with ischemic small bowel and in one with cecal perforation, severe abdominal tenderness and signs of diffuse peritoneal irritation subsequently developed. Bowel sounds were variably diminished, normal or high pitched. Fifteen patients (56%) had low-grade fever that appeared to be temporally correlated with the presence of acute colonic pseudo-obstruction rather than the associated illness.

Laboratory tests were not helpful in making the diagnosis, although metabolic abnormalities often were present. Leukocytosis was frequently present but was not specific for acute colonic pseudo-obstruction.

Radiographic Studies

In all cases, the diagnosis was suggested by the finding of colonic distention on radiologic examination of the abdomen (Figure 1). Cecal diameters ranged from 9 to 17 cm, with the majority (26 cases) measuring from 12 to 14 cm. Other diagnoses considered in all cases included true colonic obstruction, ischemic colitis and toxic megacolon. Free intraperitoneal air was not found on any initial film and was detected only once on subsequent examination in a patient with terminal metastatic carcinoma whose initial cecal diameter was 17 cm (patient 11). Many patients had a relative "cutoff" of colonic air at the hepatic, splenic or sigmoid flexures, although some distal air was almost always present.

Outcome of Therapy

All 35 episodes were initially managed for variable periods with level 1 treatment. Twelve episodes responded to level 1 treatment but there were three recurrences (see Table 1). One recurrence was successfully managed with level 1 treatment while the other two were treated successfully with colonoscopy (level 2). One other patient received level 1 therapy that was unsuccessful. This patient's cecum measured 17 cm at diagnosis and eventually perforated. No level 2 or 3 therapy was attempted because of the patient's terminal state from lung cancer.

Nine patients were successfully treated with colonoscopy when their cecal diameters equaled or exceeded 12 cm and had not responded to level 1 therapy during the first episode. In three patients colonoscopy was initially successful but recurrences developed. One patient (23) had a permanent resolution after a second colonoscopic decompression. Patient 26 had a second colonoscopy that was unsuccessful because of a large amount of sigmoid feces. During surgical intervention, splitting of the teniae coli was noted and a cecostomy was done. The third patient (19) had a second successful decompression, but was taken to surgery after a third recurrence one day later. During the operation, he was found to have splitting of the teniae coli and a localized area of necrosis with perforation of the cecum. A cecostomy was successfully carried out. One colonoscopic decompression was done after patient 27 had a recurrence one day after a laparotomy for cecal dilatation (no cecostomy was done). The colon remained decompressed after the colonscopy until the patient died many days later of renal failure.

We found that gross decompression of abdominal distention could not be achieved until the colonoscope was passed beyond the hepatic flexure. Once the cecum was reached, a visible decrease in the abdominal girth would occur quickly when suction was applied through the colonoscope.

Five patients eventually had a cecostomy, all of which were considered successful in achieving colonic decompression. One was carried out in a patient (19) in whom colonoscopic decompression was initially successful but who had a recurrence. Two were done after unsuccessful attempts at decompression (one in a patient [26] with a recurrence) and the other two were performed after a brief attempt at level 1 therapy without considering colonoscopy.

There were no complications from the 19 colonoscopies. Only one patient (11) died in whom colonic pseudo-obstruction was considered a major contributing factor. The overall mortality rate from all causes in the series was 30%.

Discussion

Acute colonic pseudo-obstruction has been considered a rare syndrome, but we found 27 patients with this condition in

four years at our two institutions. The condition also has been considered life-threatening, often requiring surgical intervention. In our experience, though, initial conservative therapy seemed to be effective or was unassociated with an adverse outcome. Moreover, the mortality rate attributable to pseudo-obstruction per se was low.

The major concern in acute colonic pseudo-obstruction is cecal perforation, but this concern must be balanced by the high risk of cecostomy in an ill patient with an unprepared bowel. This risk naturally has led to considering colonoscopic decompression as an alternative form of treatment. From our experience with colonoscopy in this series, we conclude the following:

- Colonoscopic decompression can be accomplished in

Figure 1.—Representative abdominal roentgenograms of two patients before (**A** and **C**) and immediately after (**B** and **D**) successful colonoscopic decompression.

most cases of acute idiopathic colonic pseudo-obstruction with only moderate difficulty despite no cleansing of the colon.

- The procedure, if carefully carried out, is not hazardous.
- Contrary to other reports,[8,9] effective decompression of the colon often required passage of the colonoscope into the ascending colon.
- The use of colonoscopy may avoid an operation in patients with massively dilated cecums and thus reduce the mortality rate.
- In addition to achieving colonic decompression, full colonoscopy can make a diagnosis of acute colonic pseudo-obstruction definitive by excluding true obstructing lesions or mucosal lesions such as ischemia.

The issue of the maximal size of the cecum that should be permitted before intervening with colonoscopy is difficult to resolve. Various authors have recommended some form of intervention when the cecum reaches 9 cm,[2,7,10,11] 10 cm[12] or 12 cm[3-5] in diameter, but the basis for these recommendations is arbitrary. Only 42 cases of perforation due to acute colonic pseudo-obstruction have been reported in the English language literature.[11] Only four reports actually record a cecal diameter before perforation (20 cm, 16 cm, 15 cm, 14 cm). Others have reported smaller cecal size at the time of the diagnosis of perforation. Because perforation can effect significant decompression, we doubt the applicability of reports of cecal size measured at the time perforation is diagnosed. Furthermore, we have found that most patients with typical, uncomplicated, acute colonic pseudo-obstruction can tolerate a cecal diameter of 14 cm, at least temporarily. Obviously, it is better not to allow this degree of colonic distention to develop or to persist for prolonged periods, as local perforation of the cecum occurred in one of our patients whose cecum had reached 12 cm in diameter.

It is unlikely that a randomized trial of various forms of treatment in cases of acute idiopathic colonic pseudo-obstruction will ever be done. Therefore, on the basis of our experience, we make the following recommendations for treatment of this condition: A trial of conservative measures—nasogastric suction, rectal tube, correction of metabolic abnormalities or discontinuation of medications that might interfere with bowel motility—is in order initially. If this approach is unsuccessful as assessed by abdominal films every 6 to 12 hours that show an increasing cecal diameter, or if the cecal diameter has reached 12 cm or more at the time of diagnosis, colonoscopy to decompress the colon should be done. Colonoscopy may have to be repeated in a select number of cases. A cecostomy should be done only if signs of possible perforation of the cecum—high fever, severe abdominal tenderness, referred rebound tenderness or loss of liver dullness—are present before colonoscopy can be done or if conservative therapy and colonoscopy are unsuccessful.

Anaphylactoid Reactions to Tolmetin After Interrupted Dosage

JOSEPH A. BRETZA, MD, *Milwaukee, and* HAROLD S. NOVEY, MD, *Orange, California*

Seven patients had anaphylactoid reactions after ingesting tolmetin sodium. In each case the reaction followed readministration of the drug after an interrupted period of at least three days and within 90 minutes of taking a single 400-mg capsule. None of the patients had had prior anaphylaxis and none were judged atopic. Skin tests to an extract of the drug (0.02 mg) were uniformly negative, whereas a higher concentration produced a nonspecific irritant reaction. In vitro tests in one patient for IgE antibodies to tolmetin and for complement activation were negative.

(Bretza JA, Novey HS: Anaphylactoid reactions to tolmetin after interrupted dosage. West J Med 1985 Jul; 143:55-59)

Anaphylactoid reactions to tolmetin sodium (Tolectin) is a recently described phenomenon that may have a higher incidence than that for other nonsteroidal anti-inflammatory drugs (NSAIDs).[1-7] Pertinent in the tolmetin-sensitive patients is that they do not have asthma or chronic urticaria. In addition, these persons previously ingested the drug with impunity but, after stopping the drug therapy for various lengths of time, had an immediate hypersensitivity reaction on first readministration. In the following report we describe seven cases of "second exposure" tolmetin reactions. One patient in whom respiratory difficulty developed with the use of tolmetin underwent an aspirin challenge test to determine whether his anaphylactoid reaction was generalized to other cyclooxygenase inhibitors. To gain insight into the pathogenesis of the reactions, selected in vivo and in vitro immunologic tests for immediate-type reactions were done.

Reports of Cases

Case 1

In August 1981, a 26-year-old student, a man with ankylosing spondylitis, ingested one 400-mg capsule of tolmetin and within 15 minutes had shortness of breath, coughing and wheezing, generalized pruritus and swelling about the lips and eyes. The patient "passed out" on the kitchen floor. He was put to bed by his wife and declined emergency treatment after recovery from the syncope. On examination in the clinic the following day, there were mild periorbital and lip swelling and generalized erythroderma. The lungs were clear to auscultation. Laboratory studies showed a hematocrit of 42% and a leukocyte count of 6,700 per μl without eosinophilia. His symptoms abated completely within 24 hours with no treatment. He had taken the medication without a day's interruption for more than two years until an episode of alcohol-induced gastritis prevented dosage the preceding four days.

A regimen of a non-prostaglandin-inhibiting drug, salsalate (Disalcid) was started that failed to relieve the patient's symptoms despite a blood salicylate concentration of 19 mg per dl. Because of his continued pain, the patient underwent an aspirin challenge test to find a safe substitute for tolmetin (see Methods and Materials and Results).

Case 2

The patient, a 52-year-old male engineer with sciatica, used tolmetin, 400-mg capsules, on a regular basis from December 1980 to May 1981. Following two epidural blocks in May 1981, he was almost painfree until November 1981. During this interval the patient took no medications. Following some lifting at work on November 4, 1981, he began to have a flare-up of his L-5 radiculopathy. Within 30 minutes of ingesting one 400-mg capsule of tolmetin, the patient had scattered welts, generalized itching and a "hot skin" sensation. He did not seek medical attention and his symptoms resolved within 24 hours. He was placed on a regimen of naproxen (Naprosyn) and had no reactions. Complete blood counts, including an eosinophil count, on specimens taken while he was on tolmetin therapy and three days after the tolmetin reaction disclosed no abnormalities.

ABBREVIATIONS USED IN TEXT

NSAID = nonsteroidal anti-inflammatory drug
RAST = radioallergosorbent test

Case 3

A 56-year-old male executive with gout used tolmetin on a regular basis until he had a remission of symptoms in April 1981. From April 1981 through January 9, 1982, he took no medications. Podagra developed and he took one 400-mg capsule of tolmetin. Within 60 minutes he had generalized itching and intense burning of his skin. Accompanying this was a generalized scarlatinalike eruption. The patient commented that it felt like "my skin was intensely sunburned." His symptoms resolved the next day without treatment. He presently uses ibuprofen without difficulty. The patient had no history of drug allergy, atopy or eosinophilia.

Case 4

The patient, a 51-year-old housewife with rheumatoid arthritis, had used tolmetin continuously since April 1981. In March 1983, she had an upper respiratory tract infection and stopped taking tolmetin for three days. She resumed the tolmetin therapy and a diffuse itching and erythematous skin eruption developed within 45 minutes of ingesting the first capsule. By 18 hours the patient noticed a diffuse maculopapular rash. Her symptoms resolved with administration of diphenhydramine hydrochloride and avoiding futher use of tolmetin. She is able to use ibuprofen without reaction. The patient had no history of adverse reaction to drugs and eosinophilia was absent in blood specimens taken during tolmetin therapy.

Case 5

A 39-year-old housewife with sciatica had used tolmetin, 1,200 mg a day, on a regular basis from March until June 1982, when she stopped because of a remission. In January 1983, she ingested one 400-mg capsule of tolmetin because of an acute exacerbation of her radiculopathy. Within 30 minutes generalized erythroderma, pruritus and dizziness developed, which gradually abated by 24 hours without treatment except bed rest. She uses aspirin and ibuprofen without untoward reactions. The patient has no history of allergies or eosinophilia.

Case 6

This man, a 59-year-old pharmacy technician with osteoarthritis, had taken tolmetin regularly for six weeks. Following cessation of tolmetin therapy, he was treated with a one-week course of naproxen, 250 mg three times a day. When naproxen therapy did not provide relief, his physician prescribed indomethacin, 100 mg daily for a week. While on a two-week vacation he used no medications, but on returning to work he had an exacerbation of his osteoarthritis and ingested one 400-mg tolmetin capsule. Within 20 minutes the patient had intense pruritus of his scalp, chest congestion, respiratory stridor and generalized skin erythema with hives.

The patient was taken to an emergency room where he was treated with 3 liters per minute of oxygen given nasally; diphenhydramine, 50 mg given intramuscularly, and epinephrine, 0.3 ml of a 1:10,000 dilution given intravenously. His symptoms abated after an hour.

Laboratory studies included diagnostic skin tests to a battery of 60 common allergens, which were negative by prick and intradermal techniques, confirming his lack of atopy. Complete blood counts both before and a week after the reaction showed no abnormalities. Blood specimens taken after the reaction were prepared for immunologic studies (see Methods and Materials).

Case 7

The patient, a 55-year-old male clerical worker with lumbar spondylosis, had chest tightness, wheezing and flushing 90 minutes after taking one 400-mg capsule of tolmetin. Before this he had not used the drug for at least six months. The chest tightness and wheezing subsided spontaneously after 20 minutes. Over the next 12 to 18 hours intense pruritus, a maculopapular rash and hives developed (Figure 1). He was treated with diphenhydramine, 50 mg three times a day, and prednisone, 60 mg initially, which was tapered over a one-week course. The patient's leukocyte count, C3, C4 and total hemolytic complement levels were normal.

The cases are summarized in Table 1.

Methods and Materials

Immunologic Tests

Diagnostic skin tests. The tolmetin skin test was prepared by dissolving 200 mg tolmetin sodium in 20 ml of a sterile albumin-saline diluent (Hollister-Stier Laboratories, Spo-

TABLE 1.—*Anaphylactoid Reactions to Tolmetin on Second Exposure*

NSAID=nonsteroidal anti-inflammatory drug

*Only concomitant drug therapy was in this patient who took allopurinol, 300 mg daily for 6 years. He was given allopurinol again, without reaction. All patients had previously ingested aspirin without adverse reactions.

kane, Wash). The capsule, without medication, was also studied and was provided by McNeil Pharmaceuticals in a pulverized form and prepared similarly in a 20 mg per ml solution.

Skin tests were done by both the prick and intradermal techniques in ten healthy volunteers who never used tolmetin and ten patients who used the medication without adverse reactions. The application of 0.2 mg equivalent of tolmetin but not capsule material produced an immediate burning and erythema in all persons. This reaction was considered an irritant one. Intradermal tests with a 1:10 dilution that injected about 0.02 mg tolmetin was nonreactive in all control subjects. All the tolmetin-sensitive patients were given a prick test of the concentrate and, if the findings were negative, were tested intradermally with 0.02 mg tolmetin and capsule material. If the capsule skin test was negative, the patients were administered the capsule orally.

Radioallergosorbent test (RAST). Conjugates were prepared with tolmetin (provided by James Dale, MD, McNeil Pharmaceuticals, Spring House, Pa), 50 mg dissolved in 5 ml of 0.1 mol per liter sodium bicarbonate and 0.4% phenol and incubated with 100 mg cyanogen bromide-activated microcrystalline cellulose directly, or coupled to human serum albumin, 500 mg in 50 μl of 0.1 mol per liter sodium bicarbonate, before incubating with the cellulose matrix. Specimens of serum, 0.1 ml each from patient number 6 and ten subjects not known to have encountered the drug who served as controls, were mixed with 0.5-ml suspensions of each of the two conjugates above and monitored in an automatic gamma counter for the ability to bind anti-IgE ^{125}I (Pharmacia Laboratories, Piscataway, NJ). A total serum IgE level was measured by the PRIST technique using the Phadebas kit (Pharmacia Laboratories).

Complement studies. A specimen of whole blood from the same patient (patient 6) was frozen and sent in that state by express mail to John G. Curd, MD, Department of Clinical Research, Scripps Clinic and Research Foundation, La Jolla, Calif, who generously carried out the following complement studies: serum levels of C1q, C1r, C1s, C2 through C9 inclusive, properdin factor B, C3b inactivation, β_1H, C1 inhibitor and activation of C4 by rocket immunoelectrophoresis for C4d and C4. The patient's specimens were obtained 48 hours after the anaphylactoid reaction for the complement studies and six weeks later for the IgE studies.

Aspirin Challenge Test

To ensure maximum patient safety, patient 1 was admitted to hospital for 48 hours. Informed consent was obtained. An aspirin challenge test was carried out in the morning in case a

Figure 1.—Photographs of patient's skin eruption about 18 hours after he ingested a single, 400-mg capsule of tolmetin (patient 7). There are both maculopapular and urticarial lesions present. Intense pruritus accompanied these eruptions.

*A positive challenge reaction is defined as naso-ocular symptoms associated with bronchoconstriction recorded by a fall in $FEV_1 \geq 25\%$ below baseline

delayed or severe reaction necessitated resuscitative personnel or equipment.

After a free-flowing intravenous line was placed, the patient was given incremental doses of aspirin (Table 2). Monitoring of the cardiovascular and pulmonary status was done as shown in Table 2.

Results

Immunologic Tests

Skin tests. The skin tests to tolmetin were negative in the tolmetin-sensitive persons at the nonirritant dose (0.02 mg applied intradermally). This lack of specific skin reactivity indicated that an IgE-mediated reaction was absent in the skin. The prick and intradermal capsule skin tests and capsule ingestion challenges were negative in the patients, thus excluding involvement of the orange-colored capsule in the anaphylactoid reactions.

RAST. For the two RAST assays, with and without binding to human serum albumin, the radioactive counts per five minutes for patient 6 were 1,027 and 1,797, respectively, and the mean counts for the ten control serum specimens were 1,433 and 966, respectively. A positive RAST is considered a count 2.5 times or greater than the mean of the controls. These results are indicative of a negative study or the absence of specific IgE antibodies to tolmetin in the serum. The total serum IgE level was 46 units per ml, within the normal range.

Complement studies. Results of 16 different assays were within the normal range. The C4d:C4 ratio was also normal. There was no evidence of complement activation.

Aspirin Challenge Test

The aspirin challenge test (Table 2) was negative in patient 1, thus showing a lack of cross-reactivity to another prostaglandin synthetase inhibitor. The patient was able to tolerate standard doses of a structurally unrelated anti-inflammatory drug (ibuprofen) without a reaction, as did five other patients who experienced adverse reactions to tolmetin.

Discussion

The reactions in each case arose shortly after ingesting a capsule of tolmetin in patients who previously used the drug safely but had interrupted dosage for from 3 days to 13 months. The reactions can be termed anaphylactoid even though only the skin appeared to be involved in four patients. The reactions were of the immediate type and so alarmed the patients that they needed no medical advice to stop further dosing with the drug. Three had life-threatening episodes but these cleared without evident sequelae.

The term "anaphylaxis" is usually reserved for immediate reactions of an immunologic basis and, whereas the reactions occurring after prior exposure suggest sensitization, we found no evidence of an allergic reaction after limited studies. Skin test reactions in the patients did not differ from those in the control subjects, and no IgE antibodies were found in serum by the RAST method. There was also no evidence of complement activation in the single patient studies. Moreover, if an IgE-mediated mechanism were present, one would expect evidence of atopy by personal or family history or by skin tests to common allergens in some of the reactors. Antibody to some tolmetin metabolites cannot be excluded by these tests, however. The ability of the patients to tolerate aspirin and other cyclooxygenase inhibitors following their tolmetin reactions places this group in a category apart from other patients, usually with underlying asthma, who cross-react with several members of this drug group.[8]

More established is the relationship between these reactors and those reported to react to zomepirac sodium. Both tolmetin and zomepirac are closely related chemically as pyrrole acetic acid derivatives. They differ only by one methyl and one chlorine atom (Figure 2). Zomepirac was withdrawn

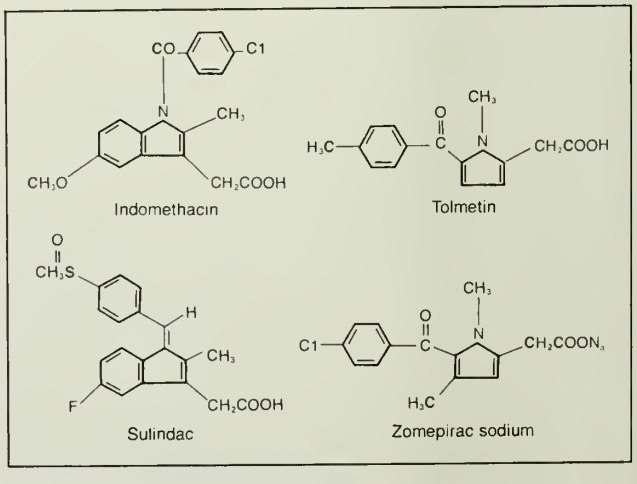

Figure 2.—Acetic acid derivations of nonsteroidal anti-inflammatory drugs. Indomethacin is an indole, sulindac is an indene derivative and tolmetin is a pyrrole analogue. Zomepirac, also a pyrrole acetic acid, resembles tolmetin both structurally and pharmacologically.

by its manufacturer on the basis of more than 1,000 suspected "allergic" reactions including five deaths, two in aspirin-sensitive patients.[9] There is a report of a case of consecutive anaphylactoid reactions to tolmetin and zomepirac in a patient who was able to subsequently tolerate aspirin.[5]

A report by officials of the Food and Drug Administration[1] noted what appeared to be an excessive number of anaphylactoid reactions to tolmetin. There is no ready explanation for the relatively large number of reactions from our two institutions. Neither rheumatologists nor pharmacists questioned here thought the drug was prescribed in an unusual manner.

Conclusion

Anaphylactoid reactions to tolmetin are manifested by clinical features varying from diffuse erythema and pruritus only to a generalized maculopapular eruption with combinations of urticaria, wheezing and syncope occurring shortly after ingesting a single capsule. They occurred in patients who had interrupted a previous course by at least three days. The patients did not have asthma or atopy. They were able to tolerate aspirin and other NSAIDs not closely related chemically. Neither an IgE-mediated nor anaphylotoxic pathogenesis could be established, but our studies were not exhaustive.

Physicians should be aware that at the start of a second course of tolmetin, severe immediate reactions may occur. There is no criterion to predict susceptible persons with the exception of a prior reaction to zomepirac. In those who have had an anaphylactoid reaction and who continue to require NSAIDs, an aspirin challenge study can be considered. Until the safety of related indole acetic acid analogues can be established, recourse to less related classes of NSAIDs (fenamates, pyrazolones, oxicoms and acetylsalicylates) appears to be preferable.

Addendum

An eighth case was encountered after this paper was submitted for publication. A 43-year-old woman had an acute episode of angioedema, erythroderma and pruritus, tachycardia, tremor and near syncope 30 minutes after ingesting a tolmetin capsule. One capsule three months earlier had produced transient urticaria, whereas no reactions occurred during her initial dosing for one week a month before that. There was no eosinophilia or history of atopy. No intolerance appeared to aspirin or ibuprofen before or to aspirin after the anaphylactic episode.

Asbestos and Gastrointestinal Cancer

A Review of the Literature

ROBERT W. MORGAN, MD, SMHyg; DONNA E. FOLIART, MD, MPH, *and*
OTTO WONG, ScD, *Oakland, California*

Exposure to asbestos is among several factors cited as possible causes of esophageal, gastric and colorectal cancer. More than 45 published studies have presented mortality data on asbestos-exposed workers. For each cohort, we listed the observed and expected rates of deaths from types of gastrointestinal cancer based on the latest published follow-up. Summary standardized mortality ratios (SMRs) were then derived. Finally, we calculated summary SMRs for total gastrointestinal tract cancer for three occupational groups: asbestos factory workers, insulators/shipyard workers and asbestos miners.

Statistically significant elevations in summary SMRs were found for esophageal, stomach and total gastrointestinal tract cancer in all asbestos-exposed workers. Esophageal cancer summary SMR remained significantly elevated when data were reanalyzed to include only those cohorts with death certificate diagnoses for cause of observed deaths. However, summary SMRs were not statistically significant for stomach and total gastrointestinal tract cancer after reanalysis. Summary SMRs by occupational group showed a significant elevation for total gastrointestinal cancer in insulators/shipyard workers. The elevation was not significant after reanalysis.

Based on the results after reanalysis, the elevations in summary SMRs for stomach and total gastrointestinal tract cancer are of a magnitude that could result from diagnostic and investigator error. We conclude that more studies are required before stomach and colorectal cancers are documented as asbestos-related diseases.

(Morgan RW, Foliart DE, Wong O: Asbestos and gastrointestinal cancer—A review of the literature. West J Med 1985 Jul; 143:60-65)

What causes gastrointestinal cancer is far from clear. Cited as possible causes are factors as diverse as diet, race, blood group, alcohol intake and exposure to asbestos. This review will examine the relationship of occupational asbestos exposure to the risk of developing carcinoma of that portion of the gastrointestinal tract including the esophagus, stomach and colon-rectum. The association of asbestos and peritoneal mesothelioma is well documented, does not involve the gastrointestinal tract and will not be reviewed here.

Esophageal cancer is a relatively uncommon cancer for which death rates have remained stable over time: 4.1/100,000 in 1955 and 4.3/100,000 in 1975, for US white men. Higher death rates have been reported in areas of Africa and Eastern Europe. In the United States, esophageal cancer is found predominantly in men and is associated with cigarette smoking and alcohol intake.

Gastric cancer is a slightly more common disease of considerable geographic variation, with some countries, notably Japan, having rates significantly higher than those of the United States. Dietary factors have been implicated in the pathogenesis of the disease. In the United States both mortality and incidence of stomach cancer in white men have fallen consistently and dramatically over a 20-year period. For example, the mortality rate dropped from 17.2/100,000 in 1955, to 8.2/100,000 in 1975.

Colorectal cancer presents an etiologic puzzle distinguished more by the number of hypotheses than by discovery of causative agents. In addition to asbestos, associations are postulated for intake of fiber, fat and specific foodstuffs. For US white men, death rates for colorectal cancer were 23.4/100,000 in 1955 and 24.4/100,000 in 1975.

Attempts to study the relationship of asbestos to gastroin-

AR = attributable risk
SMR = standardized mortality ratio

testinal cancer are frustrated by a number of factors. First, for any specific site (for example, stomach), the disease is sufficiently uncommon that few work forces can be expected to account for enough cases from which to draw conclusions. Perhaps more important, there is considerable opportunity for misdiagnosis or inaccurate certification of death, in that some gastrointestinal tract cancers will be certified as mesothelioma, and vice versa. This question has been addressed by both Newhouse [1] and Selikoff [2] in their examinations of death certificate accuracy in asbestos workers' deaths. In the Newhouse series, half of the deaths certified as gastrointestinal cancer were actually due to mesotheliomas. In Selikoff's series, only 24 deaths were originally certified as peritoneal mesotheliomas; after examining further clinical and pathologic evidence from other deaths in the cohort, investigators classified 112 deaths as due to that cause, with a pronounced reduction in number of deaths due to "all other cancer" and "all other causes."

Although diagnostic inaccuracy is troubling, it is not easily remedied. Selikoff has used "best evidence" from numerous sources, rather than the certified cause of death, to calculate standardized mortality ratios (SMRs). However, "best evidence" data cannot properly be compared with national mortality statistics, which are derived solely from death certificates. Unless one can also correct the statistics from the US reference population, comparisons are invalid because of the underlying principle that both study and reference populations should have similar ascertainment and classification of death. Another statistically questionable practice is attributing to cancer those deaths previously certified as due to a cause other than cancer, but where cancer was present (Selikoff communication quoted by Miller[3]). Again, without a similar mechanism for including cancer as a contributing cause of death in the national mortality statistics, such comparisons will either create an apparent excess of cancer in the study population or will exaggerate any excess already there.

Most of the evidence concerning asbestos and disease comes from the retrospective cohort mortality studies of asbestos-exposed workers. In all of these studies, a cohort exposed to asbestos has been identified from employment, union or other existing records and then followed prospectively over time to compare their rate and pattern of mortality with a reference population with presumably no exposure or less exposure. The reference population is frequently that of county, state or country. In general, national statistics are used because of availability and the stability imparted by large numbers. Smaller jurisdictions tend to produce statistics that can be heavily influenced by relatively few deaths, including those occurring in the work force under study.

Methods

To determine the role of occupational asbestos exposure in the risk of gastrointestinal cancer, we attempted to identify all relevant publications from the indexed literature. From each report, we extracted the details concerning cohort definition, exposure of concern and gastrointestinal cancer deaths (both observed and expected). We did not include any judgment concerning scientific merit in selecting papers to be included.

A summary of published studies of asbestos-exposed workers is presented in Table 1. Some 45 publications have described about 22 different cohorts, although within them there is some overlap. Deciphering the interwoven cohorts is complicated because in many cases a single data set has been repeatedly published, sometimes for an alternative analysis. In other cases, there appears to be no clear reason for the republication. Further confusion is introduced when papers do not specify that the data, or portions thereof, were previously reported. Some of the cohort studies reported do not mention gastrointestinal cancer, let alone specific sites, so contribute little to a quantitative analysis.

Table 2 summarizes the results of those studies which are informative as to the possible relationship of asbestos to gastrointestinal cancer. Studies were included in Table 2 when the number of gastrointestinal tract cancer deaths was available and the cohort discrete. Because of the problem of data overlap, we have used the latest published follow-up of each cohort rather than numbers from earlier papers. When available, observed deaths based on death certificates, rather than "best evidence," are presented in Table 2. Several of the studies[24,28,38] in Table 2 grouped deaths from peritoneal mesotheliomas with gastrointestinal cancers. When the actual numbers of mesotheliomas were given in the text, we deleted these from "observed" deaths. One report[33] grouped esophageal and stomach cancer deaths together for analysis. This report was not included in the calculations for those sites.

In order to provide a quantitative summary risk index for gastrointestinal cancers based on the studies reviewed, we have examined a number of statistical procedures. One procedure is the combination of relative risks based on the variance-weighted logarithms of the relative risk.[56-58] In this procedure, we can treat each cohort as a 2×2 table and the SMR as a special type of relative risk.[59] The unexposed group in the 2×2 table would be a sample of the standard population, whose sample size is the same as that of the exposed study group. This procedure, however, presents some difficulties because the number of person-years is not always presented in every study reviewed.

Another procedure of combining the risk estimates from these studies is the indirect standardization. We can view each cohort as a separate stratum; within each, certain characteristics are homogeneous (for example, study design, length of follow-up and exposure). This view is similar to that in calculating SMR within a cohort, where the strata are homogeneous with respect to age, race, sex and so forth. In the direct standardization only the observed and expected deaths are needed for the calculation. The summary SMR can be calculated as follows:

$$\text{Summary SMR} = \frac{\text{Sum of Observed Deaths}}{\text{Sum of Expected Deaths}} \times 100.$$

In essence, the summary SMR is weighted by the number of expected deaths, which is the reciprocal of the variance of the individual SMR.[58] Thus, this method is, to some extent, similar to the one based on the logarithm of the relative risks.

Needless to say, this application of the indirect standardization in summarizing SMRs from different studies is subject to the same criticisms that are often raised in summarizing

age-sex-race-specific rates in a single study. On the other hand, we know of no way to overcome the bias due to the fact that negative studies were less likely to result in published SMRs or observed and expected values, although even studies with negative findings in gastrointestinal cancer but with positive findings in respiratory tract cancer would still have a high likelihood of being published.

We have also derived summary SMRs for three major occupations: asbestos factory workers, insulators/shipyard workers and miners. In the follow-up of the New York-New Jersey cohort of insulation workers to 1976,[2] only "best evidence" calculations of observed deaths are presented (Table 3). Due to the limitations of "best evidence" data, summary SMRs were also calculated after deleting observed deaths in this cohort.

Results

Summary SMRs and confidence intervals for esophageal, stomach, colorectal and total gastrointestinal tract cancer appear in Table 3. Significant elevations in summary SMRs

PMR=proportionate mortality ratio

*Numbers in parentheses ( ) = reference numbers.

were found for esophageal (SMR = 214) and gastric (SMR = 183) cancer. Although summary SMRs for these sites were based on data from four studies, numbers were small and the 95% confidence intervals were wide. The slight excess in SMR for colorectal cancer (SMR = 113) was not statistically significant. The SMR for total gastrointestinal tract cancer (SMR = 108) was minimally but significantly elevated.

Table 4 presents site-specific summary SMRs after "best evidence" data are deleted. Esophageal cancer remains elevated (SMR = 238, $P < .05$).

Total gastrointestinal tract cancer deaths and summary SMRs for three exposure categories are presented in Table 5. Of the three occupational groups, only insulators/shipyard workers had a significant elevation in total gastrointestinal tract cancer (SMR = 132). Total gastrointestinal tract cancer was not significantly elevated in insulators when "best evidence" data were removed.

Discussion

The strongest evidence linking asbestos to esophageal and gastric cancer is a series of studies of the New York-New Jersey (NY-NJ) and US-Canadian insulation workers.[2,4-6] The summary SMR for esophageal cancer was significantly

*See comment in Author (Date)/Comments column

elevated even after "best evidence" data on observed deaths in the New York-New Jersey cohort were removed. Gastric cancer in the NY-NJ cohort contributed 19 observed deaths of 43 deaths in the calculation of the summary SMR. For the NY-NJ cohort, unfortunately, causes of death used in analysis were obtained not only from death certificates but from "best evidence." The authors did not present the number of observed deaths derived solely from death certificate information. The gastric cancer summary SMR was not significantly elevated when "best evidence" data were deleted. The same researchers found no excess of gastrointestinal cancer in either shipyard workers[7] or chrysotile miners.[8] One of the best-performed and longest-term cohort studies[9-12] has found no increase of gastrointestinal cancers of any type after more than 50 years of meticulous follow-up from first exposure.

Most of the evidence favoring an association between asbestos and gastrointestinal cancer comes from a series of studies by one group of investigators; these results must withstand critical review if a causal relationship is to be accepted. The fallacy of using "best evidence" for the cause of death has been discussed above, as a bias that inflates SMRs. In addition, repeated publishing of the same results may have created the illusion of more positive evidence than actually exists. Four cohorts have resulted in at least 14 publications (see Table 1). The original table describing the original New York-New Jersey cohort, first published in 1964, was republished in 1979 without incorporating the follow-up that had been accomplished and published in the interim. The 1976 follow-up was published in both 1979 and 1981. The 1976 follow-up of the US-Canadian cohort was published twice in 1979 and the amosite cohort follow-up of 1977 was published in 1979, 1980 and 1981. The negative studies[7,8] have not been republished.

In an earlier review, Miller[3] came to the conclusion that asbestos and gastrointestinal malignant conditions were causally related, although he did not attempt to calculate a summary risk estimate. Most of his conclusions were based upon the work of Selikoff and the review did not have the later negative studies coming from Peto,[12] Hughes[13] and Selikoff's associates.[7,8] Miller also failed to appreciate the error involved in the practice of using "best evidence" rather than the certificated cause of death for comparison with national statistics. Finally, although the review paper acknowledges the work by Newhouse in showing the extent of cause-of-death

misclassification, there was little attention paid to its potential impact on study results.

Conclusion

Malignant lesions of the lung, pleura and peritoneum have been clearly linked with exposure to asbestos. Some studies of cohorts occupationally exposed to asbestos have also found elevations in incidence of gastrointestinal cancer, while other reports have not found excesses after years of follow-up.

In an effort to summarize the available studies of gastrointestinal cancers in asbestos-exposed workers, we have calculated summary SMRs for esophageal, gastric, colorectal and total gastrointestinal tract cancer. In addition, we have derived total gastrointestinal tract cancer summary SMRs for workers exposed to asbestos in three specific capacities: factory work, shipyard/insulation work and mining.

Although there are statistically significant elevations of SMR for esophageal and gastric cancer for all groups and for total gastrointestinal tract cancer for insulators and shipyard workers, we are not convinced of the relationship to asbestos exposure, especially for stomach cancer, where the finding is inconsistent and possibly erroneous in the largest positive study. For colorectal cancer, at this time there is no discernible relationship to asbestos exposure. We hope that the occupationally exposed cohorts now under study will provide more conclusive evidence soon—refuting or supporting such an association.

Squamous Carcinoma of the Nasopharynx

PETER J. MOLOY, MD, *Long Beach, California;* YIU TING CHUNG, MD, *Los Angeles, and* PAUL B. KRIVITSKY, MD, *and* RONALD C. KIM, MD, *Long Beach, California*

Nasopharyngeal carcinoma is an unusual neoplasm among squamous cell carcinomas of the head and neck. The tumor is rare in most parts of the world but is strikingly common in several Asian subpopulations, notably Chinese in Hong Kong and Guangdong Province. The Epstein-Barr virus is intimately related to the disease and elicits the formation of antibodies that are useful for diagnosis and follow-up study. The virus has not been conclusively shown to cause nasopharyngeal cancer, however.

Histologically, nasopharyngeal carcinoma is anaplastic in 75% of cases and better differentiated in 25% of patients. All tumors are treated by high-dose irradiation to the primary site and both sides of the neck. Surgical treatment, in the neck only, is reserved for irradiation failures. The prognosis is better in patients younger than 40 years, in patients without clinical cervical nodal involvement and, unexpectedly, in patients with anaplastic tumors.

(Moloy PJ, Chung YT, Krivitsky PB, et al: Squamous carcinoma of the nasopharynx [Medical Progress]. West J Med 1985 Jul; 143:66-69)

Nasopharyngeal carcinoma is an unusual neoplasm among squamous cell carcinomas of the head and neck. The tumor has a distinctive geographic and ethnic incidence and an intriguing but ambiguous relationship with the Epstein-Barr virus (EBV). Histologically the tumor is usually anaplastic or poorly differentiated, often with an intense infiltration of benign lymphocytes (lymphoepithelioma). Treatment of the primary lesion in the nasopharynx is by irradiation alone and treatment of the neck node metastasis is by irradiation and surgical removal. We review these factors and present an interesting case.

Incidence

Nasopharyngeal carcinoma is a rare neoplasm in most parts of the world, constituting less than 0.3% of all malignant tumors and only 2% of all head and neck cancer.[1] It is, however, one of the most frequently occurring cancers among certain people of South Chinese origin, specifically those from Hong Kong and Guangdong Province (formerly, Kwangtung Province and Kwangsi Province). The disease is responsible for 57% of all cancers in men and 17% of all cancers in women in these areas according to biopsy data.[2] The highest incidence is reported in boat people living along the South China coast.[3]

Nasopharyngeal carcinoma occurs frequently in Alaskan native peoples (Eskimo, Aleut, Indian)[4] and among people of southern Chinese origin living in several other Southeast Asian countries, in California, in Honolulu and in British Columbia.[5] The risk of nasopharyngeal carcinoma developing in these populations remains high for several generations despite emigration from endemic areas. Analyzing mortality data for nasopharyngeal carcinoma in the San Francisco-Oakland area from 1958 to 1972, Buell[6] found the incidence in third-generation Chinese to be less than that in southern China, but ten times greater than that in whites.

Nasopharyngeal carcinoma is rare in whites. The disease is similarly rare in Japanese, Koreans and most blacks except for certain areas in Africa (Uganda, Tunisia) where an intermediate frequency exists.[7] It is infrequent in Indians in Singapore and Malaysia. In all population studies and whether there is a high or a low overall incidence, nasopharyngeal carcinoma is three times more common in men than in women. The significance of this sex difference is unknown. The age distribution of nasopharyngeal carcinoma is younger than for other squamous carcinomas of the head and neck and 15% to 20% of cases are younger than 30 years at onset.

Epidemiologic data are summarized in Table 1.

Etiology

Despite the high incidence of nasopharyngeal carcinoma in certain southern Chinese, the disease is not linked to the Mongoloid race per se as it occurs in non-Mongoloids and is

notably rare in several large groups of Mongols such as the Japanese. The high incidence of this cancer in southern Chinese and, particularly, in the South China coast boat people, has been attributed to the consumption of large amounts of salted fish and a vitamin C-deficient diet early in life.[3,4,8,9] An association with diet is interesting because it has been shown that carcinoma of the nasal and paranasal regions can be experimentally induced in animals fed large quantities of salted fish.[3]

The Epstein-Barr virus may play a role in the pathogenesis of nasopharyngeal carcinoma, although a causal relationship has not been conclusively shown despite intensive investigation. Data concerning antibody titers to various fractions of EBV are interesting and may provide a means of following selected patients who have nasopharyngeal carcinoma once the condition is diagnosed (see below).

Pathologic Features

According to the most recent World Health Organization system of classification,[10] nasopharyngeal carcinoma is divided into three types: keratinizing squamous cell carcinoma, nonkeratinizing carcinoma and undifferentiated carcinoma. All three types are derived from squamous cells, although epithelial cellular differentiation by light microscopy is evident only in keratinizing squamous cell carcinoma. Electron microscopy has shown a squamous cell derivation for nonkeratinizing and undifferentiated carcinomas by consistently showing desmosomes, or intercellular bridges, and tonofilaments[11]—hallmarks of squamous cells. Tumors from individual patients are classified according to the dominant and histologic type, although features of more than one type may be present. Infiltration by mature lymphocytes is common in all three types of nasopharyngeal carcinoma, particularly in the nonkeratinizing and undifferentiated forms, and led to the earlier designation of lymphoepithelioma for these tumors. The presence of a large number of lymphocytes may represent a host immune response to the carcinoma.[11] The presence or absence of lymphocytes, however, does not influence five-year survival figures, although at three years tumors with lymphocytic infiltration seem to respond to treatment better than tumors without lymphocytic infiltration.[11]

The more anaplastic tumors (the nonkeratinizing and undifferentiated varieties) are more common than better differentiated tumors (keratinizing squamous cell variety) and together account for 75% of cases. This is true for all populations surveyed. That is, the relative proportions among cases of keratinizing squamous cell carcinoma (15% to 20%), nonkeratinizing carcinoma (40%) and undifferentiated carcinoma (40%) are similar among south Chinese, who are at high risk, and among whites and Japanese, who are at low risk for nasopharyngeal carcinoma.[11]

The histologic classification of nasopharyngeal carcinoma may be an important prognosticator of patient survival. Patients with undifferentiated tumors have been reported by some authors to have a greater likelihood of surviving five years than do patients with better differentiated tumors.[5] Other studies, however, indicate that nasopharyngeal carcinoma is a fairly uniform disease despite histologic variation and that the dominant cell type does not influence prognosis.[12,13]

Otitis media	36
Epistaxis	22
Pain	15
Headache	12

*Modified from Baker and Wolfe.[13]

Symptoms

Patients present with the symptoms to be expected from a rapidly enlarging lesion in the nasopharynx (Table 2). Local symptoms include conductive hearing loss due to serous otitis media caused by tumor obstructing the eustachian tube, epistaxis and nasal obstruction. These symptoms in an adult, especially unilateral serous otitis media, should be assumed to be due to nasopharyngeal carcinoma until proved otherwise.

About 60% of patients present with metastasis to cervical lymph nodes, particularly upper jugular nodes and posterior triangle nodes. Metastatic lesions in cervical nodes are usually large, often much larger in fact than the primary lesion in the nasopharynx.

Nasopharyngeal carcinoma grows readily along the base of the skull and can involve several cranial nerves early in the course of illness (most commonly, nerves V, VI, IX, X, XI and XII). Direct intracranial extension via these cranial nerves and the foramina through which they pass is a particularly common growth pattern (see Report of a Case below). Patients occasionally present with evidence of distant metastasis, usually to lung or bones, along with local symptoms in the nasopharynx.

Diagnosis and Staging

Diagnosis requires histologic documentation by biopsy and staging relies importantly on radiographic studies to de-

fine the extent of disease. Multiple plain radiographs (including axial views) permit the diagnosis in most instances, but in all cases the computed tomographic (CT) scan will yield valuable information.[14] The CT scan can show the extent of soft tissue involvement in the neck and unsuspected central nervous system extension from the nasopharynx. In addition, the CT scan is more sensitive for detecting small primary lesions in the nasopharynx than physical examination or plain radiographs. Complete radiographic studies including CT scan should be done before a biopsy because the biopsy procedure itself leads to edema and inflammation that will distort radiographic findings for several weeks.

Relationship of Epstein-Barr Virus to Nasopharyngeal Carcinoma and Serologic Tests

The EBV is a small DNA virus resembling the herpes simplex virus. It has been proved to be the causative agent of infectious mononucleosis and African Burkitt's lymphoma. The EBV may play an important role in the pathogenesis of the undifferentiated varieties of nasopharyngeal carcinoma. This possibility is supported by the finding that serum specimens from most patients with nasopharyngeal carcinoma contain antibodies to EBV antigens.[14] These antibodies are found in all populations, not just southern Chinese. The incidence of "false-positive" anti-EBV antibody titer elevation is 5% or less among healthy volunteers and patients with other head and neck squamous cancers.[15]

Anti-EBV antibody profiles correlate well with undifferentiated and nonkeratinizing tumors but not with keratinizing tumors. This is not surprising because the EBV itself has not been found in association with keratinized, well-differentiated nasopharyngeal carcinoma with any regularity, but is almost always found in patients with the undifferentiated types of nasopharyngeal carcinoma.

Henle and Henle[16] have shown that rising anti-EBV antibody levels may signal recurrence of tumor before it is clinically evident. The same investigators have also shown that, in untreated patients, antibody titers increase as the stage of the disease advances. Titers rise especially as the tumor burden increases in the form of distant metastasis.

These data are of clinical importance. Early identification of residual or recurrent tumor is difficult to detect clinically and serologic testing may aid in the diagnosis before the disease is clinically apparent and while the tumor burden is small. Serologic testing may also be helpful in identifying nasopharyngeal carcinoma as the source in patients who present with a lump in the neck of occult origin.[16]

Treatment and Prognosis

Treatment of a primary lesion in the nasopharynx and of all direct extensions from the primary is by radiotherapy. From 6,500 to 7,000 rads are delivered by external beam through portals that include all of the nasopharynx, adjacent skull base to the level of the sella turcica and cervical lymph nodes (both sides).[18] Patients with cervical nodes clinically showing metastasis also receive 6,000 rads to lower cervical and upper mediastinal nodes.

Unlike other squamous carcinomas of the head and neck, cervical node metastasis in cases of nasopharyngeal carcinoma usually responds favorably to radiotherapy.[15] Surgical treatment in the form of radical neck dissection is used only in relatively uncommon cases in which patients are not cured by radiotherapy and in patients in whom regional nodal disease develops following a course of irradiation.

The overall five-year cure rate is about 50%.[18] Survival is distinctly better in younger adults (age, 20 to 49) than in persons older than 50 years.[5] Cure rates do not correlate closely with the presence or absence of clinically positive lymph nodes unless the nodal disease is advanced.[13] Survival does correlate with the extent of local tumor invasion,[17] and small lesions (stages T_1 and T_2) have an overall five-year cure rate of 60% versus 44% for larger (stages T_3 and T_4) lesions.[13] Most important, cure rates for anaplastic carcinomas (nonkeratinizing and undifferentiated) are consistently reported to be better than for well-differentiated (keratinizing squamous cell) carcinoma. Dickson[5] reports five-year cure rates of 42% to 52% for nonkeratinizing and undifferentiated carcinomas versus 22% for keratinizing squamous cell carcinoma.

Report of a Case

The patient, a 39-year-old Filipino man, presented in 1969 with a two-week history of right-sided hearing loss and occasional mild epistaxis. A small T_1 lesion was found in the right lateral nasopharynx on indirect mirror examination. No adenopathy was felt in the neck. Biopsy specimens from the nasopharynx showed undifferentiated squamous carcinoma with moderate lymphocytic infiltration. Treatment consisted of the administration of 5,500 rads to the nasopharynx and both sides of the neck.

He was asymptomatic until 1977 when diplopia on right lateral gaze was noted. Paresis of the right true vocal cord developed the following year along with absent gag reflex. In 1979-1980 paralysis of the right side of the tongue was noted. On examination of the nasopharynx, neck and lungs, no abnormalities were found and CT scans done in 1979 and 1980 were negative. The patient was initially thought to be suffering from a radiation-induced cranial neuropathy. In 1981, however, a repeat CT scan showed multiple intracranial masses involving all three cranial fossae, especially in the cavernous sinus area (Figure 1). A biopsy of the nasopharynx was done on several occasions with negative results. A transsphenoidal biopsy specimen was then obtained that showed poorly differentiated squamous carcinoma, which was identical to the original tumor found in 1969.

The patient was given 5,040 rads via lateral brain ports. He died five months later of aspiration pneumonia. An autopsy showed good response of tumor in the central nervous system, but malignant cells were identified in the right sigmoid sinus, the right trigeminal nerve root and in the ventral right cerebellum. There was no evidence of distant metastasis.

Comment

The tumor in this man was slow growing despite anaplastic morphology and remained radiosensitive for many years. It was locally invasive for 13 years without regional or distant metastasis. Eventually, however, tumor spread into all three cranial fossae by direct extension through foramina in the base of the skull (Figure 2). In retrospect, we think that serial antibody titers to EBV might have led to an earlier diagnosis of local recurrence. It is impossible to know if the

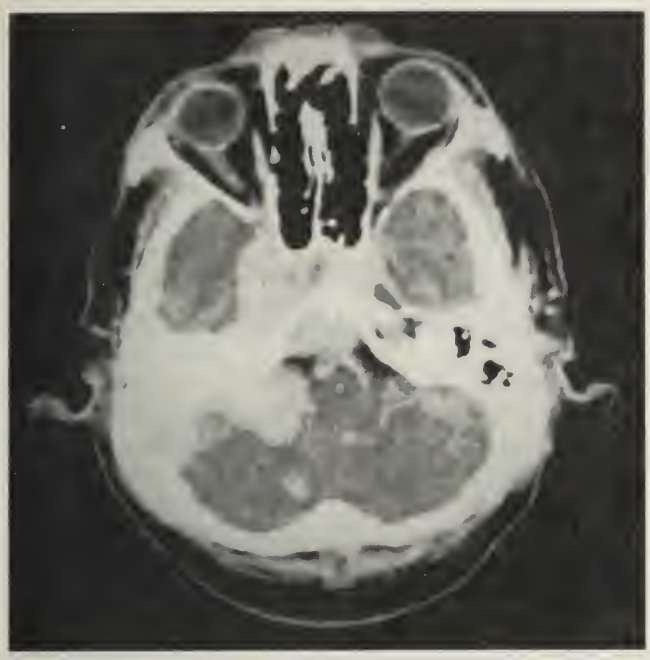

Figure 1.—Computed tomographic scan of the head showing multiple intracranial implants.

Figure 2.—Large anatomic cleft at the base of the skull (arrow). This cleft extends from the jugular foramen to the foramen lacerum and includes the petrosquamous suture. Nasopharyngeal carcinoma can invade through this area easily without producing radiographically detectable bony erosion.

tumor cells can persist for as long as one year following radiotherapy, especially in as slow growing a tumor as was present in this patient.

Summary

Nasopharyngeal carcinoma is common in people of southern Chinese origin and rare in most other racial groups. Although the cause is unknown at this time, the disease has been linked etiologically with the Epstein-Barr virus, with a diet high in salted fish and with vitamin C deficiency. Although the EBV has not been definitively shown to be a cause of nasopharyngeal carcinoma, antibodies develop to various fractions of the virus that fluctuate with interesting relationships to the course of illness in many patients.

The tumor may be histologically moderately well differentiated or well differentiated and show keratin pearl formation but more commonly is anaplastic. The histologic type bears on the prognosis because the five-year survival of patients with anaplastic tumors is better than that of better differentiated tumors, probably because of the greater radiosensitivity of anaplastic tumors to radiotherapy.

Diagnosis is based on tissue biopsy and staging on radiologic determination of the extent of tumor involvement (CT scan). Treatment of the primary neoplasm in the nasopharynx is with radiotherapy (6,500 to 7,000 rads by external beam). The neck is also treated with radiotherapy, with surgical intervention reserved for patients who have recurrence in the neck following radiotherapy.

Nasopharyngeal Carcinoma

JOHN H. C. HO, MD, DSc, FRCP, FRCR(D&T), *Kowloon, Hong Kong*

Substantial advance has been achieved in our knowledge of nasopharyngeal carcinoma within the past two decades. Elsewhere in this issue Moloy and co-workers have presented a paper on the subject. I will present a review of the recent achievements and suggest goals for future research.

Pathology

There is no longer any disagreement that the predominant malignant tumor arising in the nasopharynx of people of all races is a carcinoma of the squamous cell type, although squamous differentiation may not be evident under light microscopy in a proportion of cases if only small biopsy specimens are available for examination. Under electron microscopy, however, features of squamous differentiation can be regularly detected even in such specimens. The nasopharynx is a part of the Waldeyer's lymphoid ring. Consequently, the presence of lymphocytes in the stroma of the primary tumor or its metastasis in lymph nodes is to be expected. In its metastasis in nonlymphoid tissue such as the liver, however, lymphocytes are either absent or scanty although features of the so-called lymphoepithelioma are present in the primary tumor and metastatic lesions of cervical lymph nodes.[1,2] Therefore, the degree of lymphocytic infiltration in biopsy specimens taken from the primary tumor or metastatic nodes cannot be taken to be a guide to prognosis. A nasopharyngeal or even a nodal biopsy specimen is only a tiny fraction of the whole disease, in which islands of keratinization may be found among sheets of anaplastic undifferentiated carcinoma cells, and approximately one quarter of classical squamous cell carcinomas show areas of undifferentiated structure.[3] It is, therefore, not unexpected that in careful studies of large series of cases neither the degree of lymphocytic infiltration nor the dominant histologic pattern has been found to be useful in indicating prognosis or in planning treatment.

Etiology

From current epidemiologic and experimental data the most tenable etiologic hypothesis is one that postulates the involvement of three major risk factors: (1) a genetically determined susceptibility that allows an Epstein-Barr virus (EBV) infection in early life of the type that permits (2) the integration of the genomes of the virus into the chromosomes of some nasopharyngeal epithelial cells, priming them for (3) neoplastic transformation by some environmental nasopharyngotropic carcinogen or carcinogens that have gained entry into the infected cells. Alternatively, the environmental agents may trigger the viral genome in the cells to oncogenic activity.[4] It must be said, however, that the only evidence suggesting that EBV may be a cofactor in the genesis of nasopharyngeal carcinoma is the regular finding of the DNA of the virus in undifferentiated and poorly differentiated nasopharyngeal cancer cells. Whether it plays a causal role or exists in the cells as a passenger is not known. The virus is ubiquitous, yet a high frequency of nasopharyngeal carcinoma is found only in certain ethnic groups. This suggests that whatever its role in the cause, it can only be a cofactor.

The etiology of nasopharyngeal carcinoma is very likely multifactorial; hence, as long as an environmental factor is an essential cofactor, prevention is possible. Epidemiologic data have favored ingestants rather than inhalants as likely risk factors in southern Chinese. Among ingestants salted fish (prepared by salting and drying) is most suspected to be a major risk factor.[5] It was until two to three decades ago traditionally fed to southern Chinese in Hong Kong from early childhood for economic reasons and taste. The suspicion of its causal role was first raised in 1971[6] and has received strong support from the findings of two recent case-control epidemiologic studies. In one study, 100 Chinese patients with nasopharyngeal carcinoma and 100 neighborhood controls in Malaysia were studied.[7] Analysis of the data showed that daily consumption of salted fish in childhood carried a relative risk of 17.4 (95% confidence interval = 2.7, 111.1) compared with nonconsumption. The other study involved 250 incident cases of patients younger than 35 years and an equal number of friend controls in Hong Kong. The data showed that the relative risk for consuming the food at least once a week compared with less than once a month at age 10 years was 37.7 (95% confidence interval = 14.1, 100.4) (M. C. Yu, J. H. C. Ho, S.H. Lai, et al, unpublished data*). Because the subjects were young, many had mothers who could be

*The survey itself was completed in November 1983. A preliminary report will appear in a National Cancer Institute monograph on the proceedings of the Fourth Symposium on Epidemiology and Cancer Registries in the Pacific Basin held in Kona, Hawaii, January 16-20, 1984 (in press). The title of the paper is "The Epidemiology of Nasopharyngeal Carcinoma in Malaysia and Hong Kong" and the authors are M. C. Yu, J. H. C. Ho, B. E. Henderson and R. W. Armstrong.

VCA = viral capsid antigen

separately interviewed to check on the data obtained from their children. It is estimated from the latter study that more than 90% of cases of nasopharyngeal carcinoma in young Hong Kong Chinese could be attributed to consuming salted fish during childhood. In both studies the cases and controls were sex and age matched to within five years. As other more nutritious foods have become readily available and salted fish has become more expensive than chicken, the traditional habit of Hong Kong Chinese feeding their children salted fish is fast disappearing. It is tempting to suggest that the sharp progressive drop in their annual age-adjusted incidence rates during 1978 to 1981 from 41.5 per 100,000 to 25.8 for men and from 16.9 to 11.4 for women reported by the Hong Kong Cancer Registry might be related to this change of habit.

Judging from their age-specific incidence curves, the Swedes[6] and American whites and blacks[4] appear to have a different origin for nasopharyngeal carcinoma from that of Hong Kong or Singapore Chinese[8] or Chinese Americans.[4] The curves for the three groups of Chinese have a similar pattern, differing only in height. In Chinese the curves rise sharply after the third decade, whereas those for the non-Chinese groups show a rise after the fourth or fifth decade. If we consider the latency period—that is, the period between carcinogenic initiation and clinical manifestation—in nasopharyngeal carcinoma to be about 20 to 30 years, we should look for environmental initiators operating during early childhood in the case of Chinese and in the non-Chinese groups during their late teens and early adulthood. The Alaskan native population has a curve pattern resembling that for Chinese, but Tunisians have a bimodal curve, with the early peak at the second decade.

The rapid advance in cytogenetics and recombinant DNA technology has afforded us an opportunity to look for oncogenes in nasopharyngeal cancer cells. Their identification may help us to understand how normal nasopharyngeal epithelial cells may be transformed into carcinoma cells. It may also open new frontiers in the diagnosis and management of cases of nasopharyngeal carcinoma.

Diagnosis

The symptoms of nasopharyngeal carcinoma are well known. It is the unawareness of the disease in low-incidence areas that causes undue delay in its diagnosis. Moloy and colleagues remind us that serous otitis media may be a presenting manifestation of nasopharyngeal carcinoma. In places where both pulmonary tuberculosis and nasopharyngeal cancer are prevalent, blood-stained morning sputum due to coughed-up postnasal drip is often a cause of delay in diagnosis. Patients are usually investigated first for pulmonary tuberculosis and may be treated for it when they have shadows on their chest radiographs because of past infection. A delay of three to six months is not unusual in such cases. Nasopharyngeal cancer is not thought of until other symptoms and signs of it appear. Cervical lymph nodal enlargement is the most frequent first symptom. Because the cancer is painless, except in the presence of concurrent infection, it is often not noticed by a patient, especially if he or she has a fat neck, until there is a large tumor. Sometimes the primary tumor in such a case may not be found even by computed tomographic (CT) scan if it is small or flat. In the presence of a hypersensitive gag reflex, the nasopharynx may be examined by fiberoptic nasopharyngoscopy or inspected by the use of a Yankauer speculum if the tumor is suspected to be in the fossa of Rosenmüller. The speculum allows biopsy of the fossa under direct vision after topical anesthesia has been applied. If results of the nasopharyngeal biopsies are negative, any enlarged node should be removed and imprint smears made from it for staining for the nuclear antigen of Epstein-Barr virus (EBNA)[9] in the tumor cells before submitting the specimen for histopathology. If the EBNA test is positive, the primary tumor is most likely nasopharyngeal carcinoma, especially if the enlarged node is in the spinal accessory chain. The close association between nasopharyngeal carcinoma and Epstein-Barr virus allows EBV serology to be used in screening for the cancer among high-risk persons, such as first-degree relatives, especially siblings, of patients in high incidence areas.[10] An elevated serum titer of IgA to the viral capsid antigen (VCA) of 1:10 or greater may be the first indication of subclinical nasopharyngeal carcinoma. For such a case, multiple nasopharyngeal biopsy specimens are warranted even in the absence of symptoms or a demonstrable tumor, especially if the titers of other EBV-specific antibodies are also elevated. After specific treatment, EBV serology does not seem to reflect the state of the tumor burden to the same acceptable degree of reliability as before treatment. Hence it is of only limited help in following progress in individual patients. Actually, the production of antibodies to the various EBV-specific antigens is influenced by many factors other than the availability of EBV-specific antigens. In pretreatment cases of stage I nasopharyngeal carcinoma, the false-negative rate may be as high as 12% when the diagnostic titer of IgA anti-VCA is set at greater than 1:5. The false-positive rate is about 10%, which reflects the presence of other tumors.

The value of CT scan is in showing involvement of the soft tissue in the parapharyngeal retrostyloid and prestyloid spaces, the retropharyngeal space and the neck. Primary tumor extensions through the fissures and foramina at the base of the skull to the cranial cavity, the paranasal sinuses and the orbits are clearly shown by CT. However, for showing a small tumor in the nasopharynx, CT is clearly useless as are plain radiography and conventional tomography. In differentiating between cranial nerve involvement by recurrent tumor and irradiation neuropathy, and between temporal lobe irradiation encephalopathy and other nonneoplastic neurologic disorders and meningeal metastasis, CT scan is invaluable. Incidentally, genuine blood-borne metastasis has not been encountered in the brain, although it is not immune to invasion by adjacent meningeal metastasis or cranial extension of the primary tumor. For finding soft tissue involvement or an abnormality in the brain, magnetic resonance imaging is superior to CT. However, magnetic resonance imaging does not show up bones but only the marrow within them.

Staging

We have at present no universally accepted stage classification for nasopharyngeal carcinoma. This is hampering clinical research on the cancer, because no meaningful intercenter or even intracenter comparison of treatment results is possible. A good stage classification is one that gives an accurate indication of the prognosis and the extent of the disease to guide treatment planning. It must provide clear and practical definitions of the anatomic limits and criteria for the various stages. Without such a classification, no meaningful clinical trial can be mounted. Of the number of stage classifications that we have at present, the one formulated by the International Union Against Cancer (Union Internationale Contre le Cancer, UICC), and that by the American Joint Committee for Cancer Staging and End-Results Reporting (AJC) are more widely used than the others, but neither is satisfactory. In the AJC classification, the inferior limit of the nasopharynx is defined as level with the plane of the hard palate. This plane can only be observed in a lateral radiograph of the nasopharynx, however. It cuts across the lower part of the torus tubarius and the fossa of Rosenmüller to reach the posterior wall of the nasopharynx above the tubercle of the anterior arch of the atlas vertebra. To most clinicians the nasopharynx is that part of the pharynx situated above the posterior margin of the soft palate in its resting position and hidden from view through the opened mouth. This definition is much more practical and is adopted by the Ho classification.[11] In the UICC classification, the posterosuperior wall is defined as extending from the level of the junction of the hard and soft palates to the base of the skull. This definition of the lower limit of the posterior wall is vague and presumably it corresponds to the level of the lower margin of the basiocciput and the anterior margin of the foramen magnum. If so, it is about the same level as the lower limit defined in the AJC classification. In both classifications, T_1 is defined as tumor confined to one site or region, presumably one wall, and T_2 to two sites or regions. The limits of the primary tumor within the nasopharynx are not easy to ascertain, even for an expert. Furthermore, a carcinoma may occur submucosally and not be readily visible. The diagnosis in such a case is established by biopsy. Submucosal infiltration may occur at some distance from the macroscopic tumor. The fossa of Rosenmüller is in fact astride both the lateral and posterior walls and it is a common site of origin of the primary tumor. Consequently, a small tumor there may be reckoned to have involved two sites. It is therefore suggested that T_1 and T_2 should be combined as T_1, as in the Ho classification. From the point of view of correlating with the prognosis, the T_3 in both the UICC and AJC classifications could well be downstaged to T_2; T_4 with tumor involvement of bones below the actual base of the skull downstaged to T_3 and the rest, such as involvement of the actual base of the skull and cranial nerves at or above it, to remain as T_4. In this respect involvement of cranial nerves at the retrostyloid space should be considered T_4 involvement because the upper limit of the space is the jugular foramen at the base of the skull. Involvement of the hypopharynx should also be staged T_4 because it carries a very poor prognosis. The nodal staging in the UICC classification is designed primarily as a guide for surgical treatment by block dissection, whereas radiation therapy is the primary treatment of choice not only for the primary tumor in cases of nasopharyngeal carcinoma but also cervical nodal metastases. They are staged by UICC according to the laterality of the involvement and mobility of the involved nodes. Because the nasopharynx is a midline organ with bilateral lymphatic drainage, the cervical nodes should always be treated on both sides and according to the level of involvement, which corresponds better with the prognosis than laterality or mobility of the nodal involvement.[12]

The AJC classification included a measurement of the diameter of the involved nodes, with a diameter of between 2.9 and 3.0 cm as the cut-off point between N_1 and N_2 and between 5.9 and 6.0 cm as that between N_2 and N_3. Measurements of the diameters of cervical nodes, especially the deep-seated ones, are most of the time estimated subjectively. They are hence very inaccurate. It is easier to see and feel whether the lower poles of the enlarged nodes have extended below the neck crease at or just below the thyroid notch. The crease is taken arbitrarily to be the boundary between N_1 and N_2 regions in the Ho classification.

Treatment

The treatment results should be better now that we have the CT scanner to help us detect previously undetected soft tissue involvement to reduce geographic miss. With the availability of the computerized radiotherapy planner, a better dose distribution in the target volume is expected with reduction of dose to normal vital organs such as the brain stem and spinal cord and important organs such as the eyes. Radiosensitizers and radioprotectors are still in the development stage, and hyperbaric oxygen is a disappointment. Prophylactic irradiation of apparently uninvolved cervical lymph nodes has been shown to be unnecessary if a patient can attend regularly for follow-up.[5,12] Chemotherapy has only limited success in treating visceral metastasis, with a response rate of about 30% with the various agents that have been tried. Primary tumor and bone metastases appear to be almost unresponsive. Although distant metastasis presents a problem, the predominant site of metastasis is in bone where it is most resistant to chemotherapeutic agents. The control of the primary tumor is not just a matter of increasing the irradiation dose. There is a limit, around a time and dose fractionation factor of 108—that is, around 6,600 cGy (centiGray) over six weeks—beyond which the tumor control curve tends to level off and the morbidity curve rises sharply. As the superior margin of the treatment field is above the sella turcica and covers the sphenoid sinus, a potential site of tumor spread, part of both temporal lobes and the pituitary-hypothalamus axis would be within the target volume. In long-term survivors we are seeing complications arising from the heavy irradiation of these parts. Irradiation myelopathy is now rarely encountered because of good shielding of the spinal cord by using an anterior cervical field with a median spinal cord shield and accuracy of beam direction by the use of a transparent Perspex shell specially made for patients to wear to facilitate setting up.

Control of the primary tumor needs further research. Even in stage I cases there is a five-year cumulative primary tumor recurrence rate of 21%.[13] The overall five-year actuarial survival rate for stages I through IV cases is about 45%, and the relapse-free survival rate after initial treatment is 33%. In stage I cases, the corresponding rates are 80% and 63%.

Patients with primary tumor recurrence often benefit from a second course of radiotherapy, but the rate of late complications such as temporal lobe, brain-stem and cranial nerve (most commonly the 12th, 5th and 6th) irradiation neuropathy, temporomandibular joint capsular fibrosis and perceptive deafness would be higher. By proper shielding of a large part of the oral tongue and minor salivary glands, dryness of the mouth can be minimized. By attention to oral hygiene and the use of fluoride gel, less irradiation dental caries is expected. Prevention is better than cure and for nasopharyngeal carcinoma, prevention is probably not a too-distant possibility.

Clinicopathologic Conference

A Cystic Lesion in a 55-Year-Old Man

Discussants

JIM AMERIAN, MD; IAN RENNER, MD; WILLIAM BOSWELL, MD, *and* TELFER REYNOLDS, MD

An edited transcript of Medical Grand Rounds held at the Department of Medicine, Los Angeles County-University of Southern California School of Medicine, Los Angeles, on March 14, 1984. David A. Goldstein, MD, Associate Professor of Medicine, was the coordinator and editor of this conference.

JIM AMERIAN, MD:* The patient, a 55-year-old man, was admitted after having sharp, midepigastric abdominal pain, radiating through to the back, for six days. He also had nausea and vomiting associated with some diarrhea but said he had no recent fever or chills. The patient stated that he had had a 7-kg (15-lb) weight loss during the previous three months. His appetite had been poor for about a year. He had no history of biliary disease, peptic ulcer disease, jaundice or abdominal trauma.

The medical history included three hospital admissions for episodes of alcoholic pancreatitis, the last episode six months before this admission. He said he had not traveled recently but related 15 pack-years of smoking and an intake of a quart of whiskey per week all his adult life. The patient listed his medications as cathartics and antacids (milk of magnesia and Maalox) taken occasionally and vitamins daily.

On physical examination he was well developed, thin and appeared to be in moderate distress His blood pressure was 140/80 mm of mercury, pulse 96 per minute, respiratory rate 14 per minute and temperature 37°C (99.0°F). There were no orthostatic changes. There was no scleral icterus. On examination of the abdomen there were midepigastric fullness, generalized abdominal tenderness maximal in the midepigastric area and normal bowel sounds. The liver and spleen were not palpable and no ascites was detected. There was a slight decrease in skin turgor but no spider angiomata and no palmar erythema. A stool specimen was negative for occult blood. The patient was oriented to person and place only.

Laboratory studies disclosed the following values: sodium, 141, potassium, 3.1, chloride, 103, and bicarbonate, 27 mEq per liter; calcium, 8.7, phosphorus, 1.7, glucose, 132, urea nitrogen, 10, uric acid, 5.1, and creatinine, 1.0 mg per dl; alkaline phosphatase, 179 IU per liter; total protein, 6.4, and albumin, 3.2 grams per dl; total bilirubin, 0.8, and direct bilirubin, 0.1 mg per dl; serum aspartate aminotransferase (glutamic-oxaloacetic transaminase), 15, and serum alanine aminotransferase (glutamic-pyruvic transaminase), 26 units per liter. The leukocyte count was 11,100 per μl (94% segmented neutrophils), platelets were 141,000 per μl and hematocrit, 33.9%. Serum amylase was 154 (normal, 75 to 140) and urine amylase 1,518 units per liter (normal, less than 500).

Hospital Course

The patient was diagnosed as having pancreatitis and was treated with meperidine hydrochloride (Demerol) and hydroxyzine hydrochloride (Vistaril) given intramuscularly, fluids given intravenously, thiamine, multivitamins and folate. On the second hospital day, he went into alcohol withdrawal. He was treated with oral administration of lorazepam. On the fourth hospital day, a fever of 39°C (102.2°F) developed. At this time, he had no abdominal pain.

On the sixth hospital day, his maximum temperature by mouth was 38°C (101°F). The leukocyte count was elevated at 18,400 per μl with a differential of 82% segmented forms, 7% bands, 5% lymphocytes and 6% monocytes. By the eighth hospital day, the patient was afebrile. Blood cultures were negative. The serum amylase level was 199 units per dl, urine amylase 354 units per dl and the leukocyte count was 15,300 per μl, with a differential of 89% segmented cells, 1% bands, 4% lymphocytes and 6% monocytes. On the ninth hospital day, an ultrasound study and a computed tomogram of the abdomen were obtained. Serum amebic titers were less than 1:32. On the 11th hospital day, a procedure was done.

Dr Renner, would you discuss your approach to this case and provide us your final diagnosis?

*Assistant Professor of Clinical Medicine, USC School of Medicine.

Differential Diagnoses

IAN RENNER, MD:* There are several ways to approach a case presented at these exercises. My preference is to discuss the differential diagnosis as the case presents and then to confirm or delete possibilities as the course of the illness unfolds.

Ideally, the list of diagnostic possibilities should be few; the aim of any good clinician should be to focus on the most likely diagnoses and to proceed in a logical and cost-effective manner to exclude or confirm his or her diagnostic impressions. I hold no brief for a long differential diagnosis, especially where little thought is given to ranking the likelihood of such diagnoses.

We already know from the title of this conference that a cystic lesion is present in the liver; however, only a physician gifted with precognition could have predicted its presence before the radiologic investigation. This aspect of the case will, therefore, be discussed at the appropriate time.

Our patient presented with a six-day history of symptoms characteristic of alcohol-associated chronic relapsing pancreatitis. The name itself is unfortunate and inaccurate in that it implies the absence of any acute process; I prefer the term acute-on-chronic pancreatitis. The triad of nausea, vomiting and epigastric pain radiating through to the back is usually present in such cases and is almost invariably associated with prolonged heavy drinking.

The weight loss and long-standing poor appetite are almost certainly due to chronic alcoholism and not to pancreatic insufficiency, because in the latter case enhancement of appetite is the rule, even where there is massive weight loss.

The physical findings on admission of epigastric fullness and tenderness in the presence of normal bowel sounds should at the outset suggest the possibility of a common complication of this illness, namely, a pancreatic pseudocyst. Physical examination will disclose an abdominal mass in only 50% of these patients, even though a large cyst may be present.[1]

The laboratory abnormalities include a moderately elevated serum alkaline phosphatase level at 179 IU per dl, serum albumin content depressed at 3.2 grams per dl, a decreased hemoglobin at 11.4 grams per dl, mild elevation of the leukocyte count without any left shift, an elevated mean corpuscular volume of 100 cu microns, a serum amylase level of 154 units per dl and a urine amylase value of 1,518 units per dl.

In the presence of normal transferases I would be inclined to attribute the elevated serum alkaline phosphatase value to a complication of chronic pancreatitis, namely, periductular sclerosis involving the distal common bile duct as it passes through the head of the pancreas. The low serum albumin level is consistent with levels usually observed in such patients due to poor nutrition. The anemia and moderate macrocytosis probably reflect the moderate bone marrow suppression and folate deficiency commonly seen in such cases. Marginal elevation of the serum amylase level with moderate elevation of the urine amylase content is common in this type of pancreatitis[2-4] and merely reflects the ability of the kidneys and the reticuloendothelial system to efficiently clear any modest increase in the release of amylase from the pancreas.

It is important to remember that chronic relapsing pancreatitis is lobular in distribution and does not involve the pancreas globally as is the case with acute pancreatitis. Thus, the biochemical disturbances, especially the elevation of serum amylase or lipase, may be only marginal.

At this point, I suggest that we are dealing with the following diagnostic problems:

1. Chronic alcoholism.
2. Chronic relapsing pancreatitis.
3. Probable pancreatic pseudocyst.
4. Possible periductal stenosis of the distal common bile duct due to pancreatic fibrosis.

Four days after admission to hospital and ten days after the onset of pain, a fever of 38°C developed, followed by an elevated leukocyte count of 18,400 per μl with some evidence of a left shift.

Blood cultures were done and failed to grow any organisms. No antibiotics were given at this time. In this setting, the possibility of my hypothetical pseudocyst converting to a pancreatic abscess must be considered, as fever is unusual in cases of uninfected pseudocyst.[1]

The characteristic features of a pancreatic abscess are fever, leukocytosis of greater than 18,000 per μl in a patient recovering from an attack of acute pancreatitis or, in this case, of chronic relapsing pancreatitis.[1] Our patient at this time thus fulfills all of the above criteria for possible pancreatic abscess formation.

In the 1970s and before the development of sophisticated modalities such as ultrasound and computed tomographic (CT) scans, a plain abdominal film to look for evidence of pancreatic calcification, displacement of any gas-filled viscus and the "soap bubble" pattern characteristic of retroperitoneal sepsis would have been mandatory. In addition, an upper gastrointestinal series would have been carried out to more clearly identify any space-occupying lesion compressing the stomach or duodenum. It is still essential to get plain abdominal and chest x-ray films in all such cases, especially as a pleural effusion will be present in 20% to 35% of patients who have a pseudocyst.[5]

What is surprising to me is the five-day delay in doing an abdominal ultrasound study after the patient had a fever spike of 39°C on the fourth hospital day. I have looked up the date the procedure was done, thinking that the onset of fever must have occurred on a weekend when radiologists are usually found basking in the sunshine; this was so. On the sixth day of his hospital course, however, the patient was still febrile with a leukocyte count of 18,400 per μl. By this time, at least, an ultrasound study should have been done. Blood specimens were obtained for culture, which failed to grow any organisms, and no antibiotics were given. On the ninth hospital day and 15 days after the onset of pain, nausea and vomiting, the long-awaited ultrasound study was carried out. The following day, a CT scan of the abdomen was done and on the 11th hospital day, he had a "procedure."

Dr Boswell, will you describe the ultrasonographic and CT scan findings, please?

Radiologic Findings

WILLIAM BOSWELL, MD:* Thank you, Dr Renner. As radiologists, it is our job to look beyond the obvious findings on a film and assist specialists and subspecialists in solving a diag-

*Associate Professor of Medicine, Division of Gastroenterology, USC School of Medicine.

*Associate Professor of Radiology, USC School of Medicine.

nostic dilemma. Looking beyond the obvious, I found that although the fifth hospital day occurred on a weekend, it was cloudy during this entire period and even a radiologist could not be found basking in the sun. Let us now review the patient's x-ray findings.

A chest x-ray film was taken at the time of admission and was normal. No evidence of pleural effusions, areas of atelectasis or infiltrates were seen. An ultrasound study of the pancreas was done on the ninth hospital day. The gallbladder was contracted and poorly seen, presumably because the patient had eaten recently. The common bile duct was visualized and measured 7 to 8 mm in diameter, the upper limits of normal. The pancreas was relatively normal in size but displayed decreased echogenicity consistent with pancreatitis. No specific fluid collections were noted in the region of the pancreatic bed.

An 8.1 by 4.1 by 7.8 cm hypoechoic lesion was identified cephalad and anterior to the pancreas, possibly involving the left lobe of the liver (Figure 1). The interface between the lesion and the liver was irregular. The lesion itself appears to be surrounded on three sides by liver parenchyma. There was a sharply marginated back wall to the lesion with good through-transmission, suggesting primarily a fluidlike collection. Some echoes were noted within the lesion, possibly representing debris. The stomach was noted to be lateral to the lesion.

On the tenth hospital day, a CT scan of the abdomen was done. Orally administered contrast material outlines the stomach and gastrointestinal tract. A well-circumscribed lesion is seen in the region of the left lobe of the liver (Figure 2), surrounded almost entirely by liver parenchyma except on its inferior aspect. The CT scan numbers are in the range of 10 to 20, slightly higher than is expected for a water-dense material. Within this collection, there is some material that is slightly higher in density. This could represent blood or debris within the fluid. The pancreas is enlarged with a low-density region seen centrally, suggesting a dilated pancreatic duct (Figure 3). A second fluidlike collection is seen in the lesser sac lateral and superior to the pancreatic tail (Figure 2). The inferior aspect of the anterior lesion, which appears to involve the left lobe of the liver, is located just anterior to the superior aspect of the pancreas. This corresponds to the findings of the pancreatic ultrasound study. The CT scan of the abdomen shows no other abnormalities.

DR RENNER: Several questions come to mind:

1. How accurate is ultrasound in detecting dilated extrahepatic ducts?

2. Can we be certain that there were no stones in the gallbladder or in the common bile duct?

3. Do you feel that the CT scan shows evidence of calcium deposits in the pancreas?

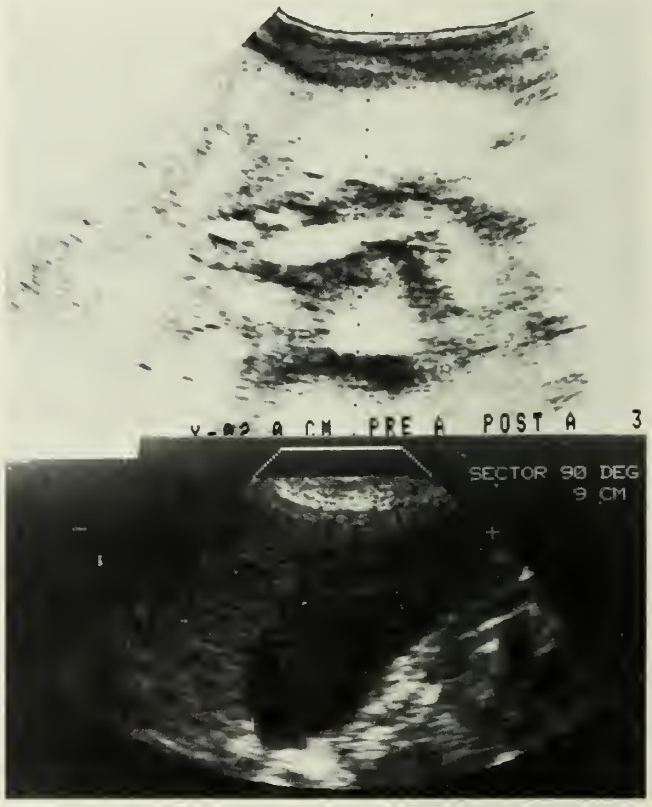

Figure 1.—Transverse and longitudinal ultrasound scans of the upper abdomen. A large, relatively hypoechoic fluidlike lesion is shown anterior and cephalad to the pancreas.

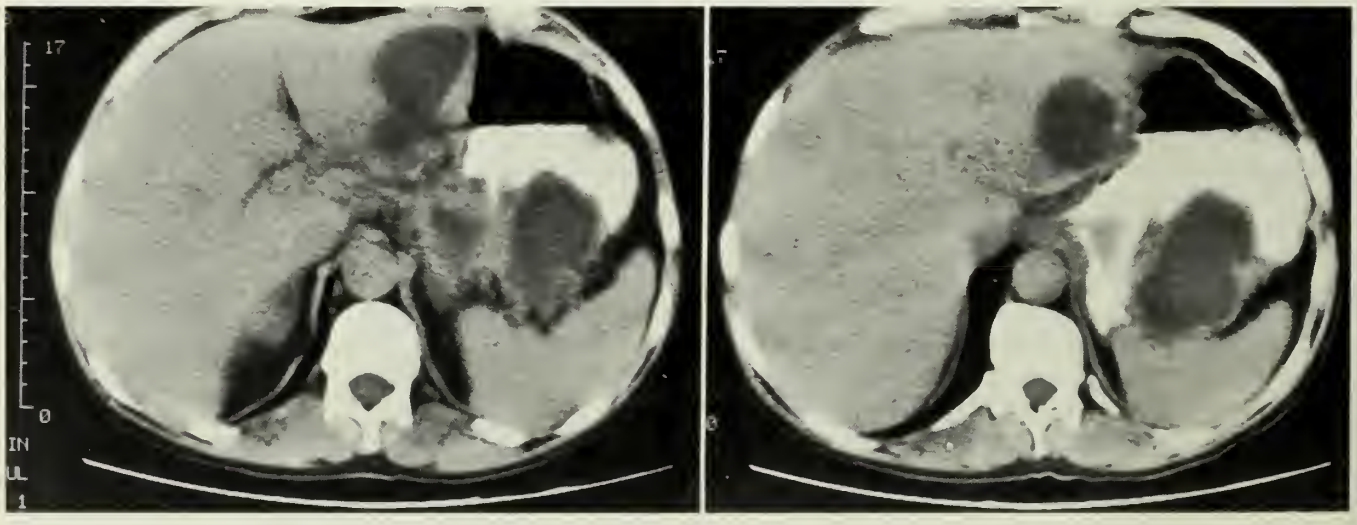

Figure 2.—Computed tomographic scans through the upper abdomen show anteriorly the fluid collection within the left lobe of the liver. Additionally, a fluid collection is seen in the lesser sac posterior to the stomach.

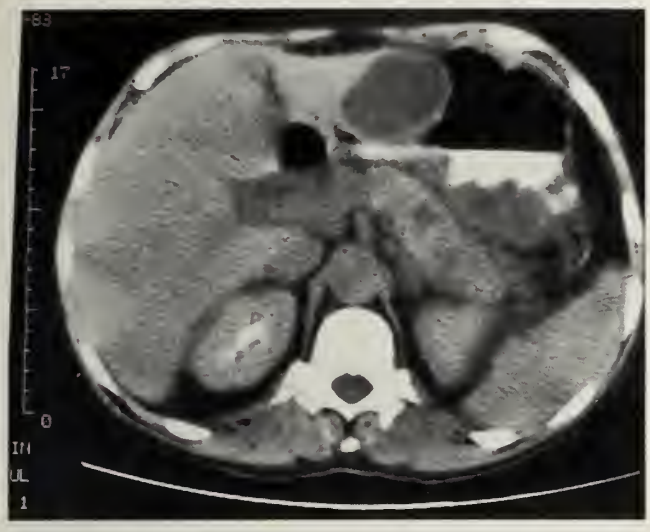

Figure 3.—A computed tomographic section through the pancreas shows a mildly enlarged tail of the pancreas in which a somewhat linear low-density area is identified, believed to be a dilated pancreatic duct. Additionally, the lower limits of the fluid collection in the left lobe of the liver are identified anteriorly. Some slightly higher density material is seen near the bottom of this lesion. The lower limits of the lesser fluid collection are also seen posterior to the stomach and anterior and lateral to the tail of the pancreas.

4. Does the failure to show any communication between the hepatic cyst and the extrapancreatic pseudocyst on the CT scan rule out their possible intercommunication?

5. Can you reliably differentiate abscess from a simple pseudocyst?

DR BOSWELL: Ultrasound is extremely accurate in assessing the diameter of the extrahepatic biliary ducts. Depending on the specific measurement used for the cross-sectional diameter of the duct, its accuracy increases or decreases. At our institution, we use 8 mm as the upper limit for a normal-sized main bile duct. A diagnostic accuracy of greater than 95% would be anticipated using 8 mm as the maximum diameter of the duct. With regard to your second question, when the gallbladder is well distended, an accurate examination should detect virtually all stones. In evaluating technically adequate scans at this institution, only 2 cases out of about 300 to 400 showed no gallstones at an operation when gallstones were reported to be evident on the ultrasound examinations. One patient had almost certainly passed a stone between the time the scan had been done and the operation. With the other patient, we do not have a specific answer for the discrepant findings. In evaluating the common bile duct for the presence of gallstones, our accuracy is much lower. In a large series at this institution, about 25% of common bile duct stones were visualized by ultrasound study. The remaining 75% were not seen for various technical reasons, usually due to incomplete visualization of the entire common bile duct.

This particular CT scan does not show any evidence of calcium deposits within the pancreas. CT scans, because of their remarkable ability to discriminate different tissues, are ideal for detecting calcium deposits within the pancreas.

The answer to your fourth question regarding the communication between the hepatic cyst and the extrapancreatic pseudocyst is easy. As the sections from CT scans are axial and not always in the plane of the different collections, it is not unexpected that a communication would be found. In cases such as these, when a communication is shown, it is more often serendipitous than expected. One might, however, demonstrate a communication between the two cysts using the skinny-needle technique by instilling contrast in one cyst and showing that contrast material flows to the second cyst.

Differentiating abscess from a simple pseudocyst may, on occasions, be simple but is more often difficult. Specific findings of debris and gas within a lesion would certainly point one toward the possibility of an abscess. A simple pseudocyst would be expected to have a well-circumscribed wall and fluid-dense material within it that is homogeneous. The most reliable way to differentiate between abscess and a simple pseudocyst is to aspirate the lesion with a 22-gauge skinny needle and examine the fluid obtained.

DR RENNER: The intriguing findings shown by both ultrasonography and CT scan do not change my initial diagnosis of pseudocyst formation due to acute-on-chronic pancreatitis with almost certain main pancreatic duct stricture and consequent ductal rupture. The diagnosis of pancreatic pseudocyst by ultrasound and CT scan is usually straightforward and is established by imaging an encapsulated cystic collection that forms as a consequence of release of proteolytic enzymes from a ruptured pancreatic duct. Pseudocysts have the striking ability to erode into the retroperitoneal space and then to appear in unusual and remote locations including even the mediastinum and the pelvis.[6,7]

Thus, renal disease may be simulated by a dissecting pseudocyst, which usually involves the left kidney,[8] whereas the lienorenal ligament provides a natural pathway for proteolytic enzymes to the splenic hilum with direct involvement of the spleen.[9] The liver, however, has no such convenient pathway for free enzymes to travel; hence, it is surprising and very uncommon for hepatic parenchyma to be involved. During the past two years, however, we have seen at the Los Angeles County-University of Southern California Medical Center two very unusual cases of solitary pseudocysts in the liver (following acute pancreatitis) shown by CT scan. In one case, no evidence of pancreatic communication was seen and the diagnosis was clinched by finding cyst fluid serum amylase levels exceeding 18,000 units per dl using the skinny-needle aspiration techniques under CT scan guidance.

The body and tail of the pancreas showed obvious enlargement with an ill-defined, irregularly dilated ductal system on the CT films. This finding is the obvious setting for ductal rupture and pseudocyst formation. I am reluctant to concede the possibility of two pathologic diagnoses in this case and, therefore, feel that the cystic lesion in the liver is, in fact, a pseudocyst. It is entirely possible, however, that the two lesions are dissociated and one must consider the differential diagnosis of cystic lesions in the liver. In brief, these include amebic abscess—an unlikely diagnosis with a titer of 1:32—and a solitary cyst of the liver, which cannot be ruled out, nor can unusual presentations of hydatid cyst, hematomas or the rare cystadenoma. None of these suggestions sway me from my initial diagnosis.

Coming back to the other abnormality observed by ultrasonography—the dilated common bile duct—again, I would be inclined in the presence of known chronic pancreatitis to stick to my original diagnosis, that the dilation is due to

periductal sclerosis. The elevated serum alkaline phosphatase level thus could be due to this lesion or to the presence of the cystic liver lesion (or to both).

The diagnostic procedure of choice, and the one that was probably carried out in this case, was skinny-needle aspiration of both cystic lesions under CT scan guidance. If I have guessed correctly, we should obtain reddish fluid from both cysts, the contents of which should show high amylase levels and an elevated leukocyte count without growth of organisms on culture.[10,11] This type of approach has the advantage of allowing us to exclude abscess formation and, according to numerous recent reports,[10-12] may be a way of determining whether a cyst will resolve spontaneously or ultimately require a surgical procedure, by observing how quickly the fluid reaccumulates.[12]

It is quite conceivable that the pseudocyst adjacent to the pancreas has become infected; this would be an unusual development, however, in view of the resolution of the patient's fever without the use of any antibiotic therapy.

Dr Renner's Clinical Diagnosis

1. Antecedent chronic alcoholism.
2. Chronic relapsing pancreatitis.
3. Peripancreatic pseudocysts.
4. Hepatic pseudocyst.
5. Probable periductular distal common bile stenosis due to pancreatic fibrosis.

DR AMERIAN: On the 11th hospital day, the cystic liver lesion was aspirated under the guidance of ultrasound; about 10 ml of foul-smelling, yellow, cloudy fluid was obtained. Cultures from this material grew 2+ *α-Streptococcus* (not group D), 2+ *Escherichia coli*, 2+ *Fusobacterium* and 2+ Gram-positive anaerobic cocci. The amylase value was 4,268 units per dl. The patient was initially treated with clindamycin phosphate and gentamicin sulfate. This antibiotic regimen was subsequently switched to cefotaxime sodium and metronidazole. He received this regimen for ten days in hospital and was then discharged home and instructed to take oral ampicillin and metronidazole for an additional ten days. At the time of discharge, his leukocyte count was 9,900 per μl with the following differential: 68% segmented neutrophils, 23% lymphocytes, 6% monocytes and 3% basophils. Except for fever on the fourth to the sixth hospital days, the patient remained afebrile with no abdominal pain.

Dr Reynolds, could you briefly discuss the management of this case?

Management

TELFER REYNOLDS, MD:* The Liver Service physicians saw this patient in consultation soon after discovery of the hepatic mass lesion. Our analysis of his illness was very similar to Dr Renner's. To the list of hepatic lesions with a relatively low CT scan density and reduced sonographic echoes, I would add malignancy, both primary and secondary. At times, neoplasms have such a uniform consistency that they give fewer sonographic echoes than does normal liver. In this patient, we thought the most likely lesion was an intrahepatic pseudocyst of the pancreas. Frankly, I would not have considered this a possibility before 18 months ago, when we saw a similar case with a 6-cm pancreatic pseudocyst that proved to be partially imbedded in the posterior aspect of the left lobe of the liver. This must not be excessively rare as the recent literature contains several reports of similar cases.[13-17] For this patient, we advised needle aspiration of the intrahepatic mass to confirm its cystic nature and to obtain an amylase level of the contents. The evidence of infected fluid was a total surprise to all of us involved with the case because fever had subsided and there were virtually no residual symptoms. The second cyst was not aspirated as it seemed certain that it was a pancreatic collection and treatment would likely be unchanged whether or not it was infected. At this point, the patient was presented at a combined medical-surgical conference and, after considerable discussion, we elected to treat him for ten days with intravenous administration of antibiotics and then to reevaluate. Several of the physicians attending the conference were skeptical of this approach and felt strongly that he should have an immediate operation for external drainage of the presumed "pancreatic abscess." Certainly most textbooks and articles on pancreatic abscess mandate surgical drainage. It was largely because of this patient's paucity of symptoms and lack of systemic evidence of sepsis that medical therapy was elected.

In a somewhat analogous lesion, pyogenic liver abscess, surgical drainage has until recently been considered absolutely essential for survival. In 1953, McFadzean and colleagues from Hong Kong reported the cases of 14 patients with pyogenic liver abscess who survived with needle drainage and antibiotics.[18] This report was largely ignored. In 1979, however, we reported the recovery of six patients who did not have surgical drainage[19] and soon after this an additional ten patients at the Kaiser Hospital in Los Angeles were reported to recover with medical treatment.[20] Our current experience is that surgical drainage is rarely needed for pyogenic liver abscess; even needle aspiration may be unnecessary if an organism has been identified in blood cultures.[21]

It is too soon to say whether a similar change in the approach to treatment of other intra-abdominal abscesses will occur. The liver is a highly vascular organ and there is no fibrotic capsule around a liver abscess so that antibiotic penetration can be expected. An infected pancreatic pseudocyst may be another matter, however, because there is a fibrous capsule and no surrounding vascularized tissue. Nevertheless, Gerzof and co-workers recently reported successfully treating 24 patients with intra-abdominal abscesses by percutaneously placed drainage catheters and parenteral antibiotics.[22] Four of these patients had infected pancreatic pseudocysts or phlegmons and three of them recovered without surgical drainage. I think it is too soon to advocate a trial of medical treatment of cases of pancreatic abscess without continuous drainage of some sort, either surgically or by a percutaneously placed catheter. It is entirely possible, however, that this sort of treatment could be successful in some patients, so perhaps it should be tried in those who are not critically ill.

Medical Practice Question

EDITOR'S NOTE: *From time to time medical practice questions from organizations with a legitimate interest in the information are referred to the Scientific Board by the Quality Care Review Commission of the California Medical Association. The opinions offered are based on training, experience and literature reviewed by specialists. These opinions are, however, informational only and should not be interpreted as directives, instructions or policy statements.*

Cranial Electrotherapy Stimulation

QUESTION:

Is the use of cranial electrotherapy stimulation considered accepted medical practice or is it considered investigational?

OPINION:

In the opinion of the Scientific Advisory Panels on General and Family Practice, Internal Medicine, Neurology and Psychiatry, cranial electrotherapy stimulation is considered investigational. This noninvasive procedure involves the application of small pulses of electric current to the patient by means of electrodes placed behind the ears. It is intended to control stress-related disorders such as anxiety, depression, insomnia and various chemical dependencies.

The scientific studies supporting the efficacy of this technique are not convincing. Few of these studies are double-blind and they fail to cite the diagnostic criteria for the disorders evaluated or adverse reactions. There is no reasonable or consistent body of information available to suggest other than placebo effects from this type of treatment.

Controlled clinical trials with larger numbers of patients conducted by experienced investigators are required before cranial electrotherapy stimulation can be considered accepted practice.

Diagnosis and Management of Lower Gastrointestinal Tract Hemorrhage

These discussions are selected from the weekly staff conferences in the Department of Medicine, University of California, San Francisco. Taken from transcriptions, they are prepared by Drs Homer A. Boushey, Associate Professor of Medicine, and David G. Warnock, Associate Professor of Medicine, under the direction of Dr Lloyd H. Smith, Jr, Professor of Medicine and Chair of the Department of Medicine. Requests for reprints should be sent to the Department of Medicine, University of California, San Francisco, School of Medicine, San Francisco, CA 94143.

DR SMITH:* *Our topic for this conference is "Diagnosis and Management of Lower Gastrointestinal Tract Hemorrhage" and John P. Cello, MD, will give this presentation. Dr Cello is Chief of Gastroenterology at San Francisco General Hospital and an Associate Professor of Medicine.*

Historical Background

DR CELLO:† The colon and its diseases played a central role in ancient Egyptian medicine. All vessels, including those carrying blood, mucus, urine, semen, water and air, were believed by the ancient Egyptians to come from the heart, but they were felt to have a second assembly center around the rectum. Blood, it was believed by the Egyptians, could become flooded with *ukedu* or feces and carried throughout the body. They were so concerned about this dangerous material that ritual purges and enemas played an essential role, both during life and after death, for the Egyptians. During the next 2,000 years of western civilization, healers were preoccupied with the importance of colonic function, so much so that our principal title of "physician" is derived from "one who administers physic"—that is, enemas and laxatives.

Differentiating Upper From Lower Gastrointestinal Tract Bleeding

The most alarming of colonic dysfunction symptoms experienced by patients is the passage of bright red blood per rectum. I will review some of the most recent advances in our approach, both diagnostically and therapeutically, to patients with significant hematochezia.

It would seem very easy to differentiate upper from lower gastrointestinal tract hemorrhage, and it is so in most patients. One can be certain that if a patient has hematemesis or melanemesis (coffee-grounds emesis), blood is passing into the gastrointestinal tract from a site proximal to the ligament of Treitz. In most instances, this bleeding is from esophagus, stomach or duodenum. Recall, however, that nasopharyngeal, tracheobronchial or pancreaticobiliary systems likewise drain into the proximal gastrointestinal tract and on occasion these may be the sites of hemorrhage. Bleeding from these sites may be manifested by hematemesis and melanemesis. The companion to hematemesis and melanemesis usually indicating a source of bleeding in the proximal gastrointestinal tract is melena, the passage of dark liquid, black, tarry, foul-smelling stools. In some instances, however, melenic stools are actually from cecal bleeding with slow intestinal transit. What about hematochezia, bright red blood per rectum? In most instances it signifies bleeding from the distal bowel, particularly the distal small bowel or the colon. However, in about 10% to 15% of patients with vigorous hematochezia, the bleeding lesion is actually from the proximal gastrointestinal tract. The most common lesion of the upper gastrointestinal tract associated with hematochezia is brisk arterial bleeding from an ulcer crater, particularly a posterior duodenal bulbar ulcer penetrating into the gastroduodenal artery. On occasion also, hematochezia can be from an aortoduodenal fistula or even from infarction of the small bowel with ileus.

Lower gastrointestinal tract bleeding is not a disease entity in itself, but is really a manifestation of a wide array of diseases that present clinically as hematochezia. The largest series to date in which the etiology of hematochezia was reviewed was by Tedesco and co-workers from Emory University in Atlanta; the series comprised 258 patients with no abnormalities found on proctoscopy (Table 1).[1] The patients were admitted to hospital, given transfusions and then, as their first diagnostic procedure, had a single-contrast barium enema followed within three to four days by an elective colonoscopy. With this approach, a third of the patients had no lesion detected. Thus, a third of these patients who were admitted to hospital with hematochezia had no colonic source for the hematochezia identified. Amost 19% had colonic diverticula alone so that in their series, diverticular bleeding was the most common identifiable cause of hematochezia. There is, however, nothing unique colonoscopically or on barium radiography to tell which particular diverticulum is actually bleeding; in fact, the only potential source for the hematochezia was diverticula noted on barium radiography

*From Tedesco et al.[1]

and colonoscopy. The diverticula were followed in terms of decreasing frequency as a source of hematochezia by large polyps, cancer, inflammatory bowel disease, diminutive polyps and angiodysplasia. These figures have changed somewhat, as we now take a different approach to the evaluation of patients with hematochezia and no abnormalities found on proctoscopy.

Diagnostic Procedures

Proctoscopy

The most important diagnostic procedure to do in patients who have hematochezia is the examination of the rectum. This must be the initial diagnostic procedure and it is usually carried out by rigid proctoscopy. One of the major difficulties that medical trainees have in doing a proctoscopy on patients with hematochezia is with misinterpreting the source of the blood coming from above the depth of instrument insertion. With brisk bleeding from a distal colonic site, retrograde passage of blood into the more proximal colon is not uncommon. In fact, blood from an anorectal lesion may flow as far proximally as the ascending colon. In doing a rigid proctoscopy with the patient in the knee-chest position, no distal lesion may be noted because of the overlying blood or debris, and an examiner may misinterpret the presence of blood from above the depth of tube insertion as representing bleeding from above that depth. It is thus extremely important to examine for hemorrhoids or rectal tears because, especially in hemodynamically trivial hematochezia, distal rectal disease is the most common cause of bleeding.

There has been a dramatic shift over the past ten years in the approach to rigid proctoscopy in most American medical training programs. Before the late 1970s, a rigid proctoscopy was routinely done on initial patient contact by the primary health care provider. It was done by students, house officers, outpatient care physicians, on the wards, in a patient's bedroom and in clinics without any special procedures or special equipment. As a consequence, nearly all health care providers, regardless of their subspecialty, were proficient in doing rigid proctosigmoidoscopic examinations. More recently in the United States there has been a shift, with proctoscopy now considered virtually a "subspecialty" diagnostic procedure. It is, therefore, being done electively in endoscopy suites by specialty physicians and fellows. As a consequence, few, if any, primary health care providers have developed or retained the skills of rigid proctoscopy. There are many reasons for this. There is the general trend towards specialization that has put every invasive diagnostic procedure into a subspecialty categorization. Health care administrators are also to blame for much of this, because the facilities on wards and in clinics for carrying out proctosigmoidoscopic examinations have been extremely poorly equipped and maintained. Proctoscopy, of course, can be a messy procedure, involves the primary physician's care and attention and it provides qualitative, nonquantifiable information. Thus, house staff and attending physicians alike tend to devolve this diagnostic procedure onto other physicians, some of whom are more than willing to accept the challenge—in exchange for an increased fee generation—using flexible fiberoptic instruments. However, I think there has been a lack of discipline by supervising physicians in not insisting that this routine extension of the physical examination be done in patients who are admitted to hospital with hematochezia.

Rigid proctoscopy is *not* a subspecialty diagnostic procedure. It has advanced considerably, with major advances in the development of plastic disposable obturators and insertion tubes that cost only $5. The illumination equipment costs about $150, so there is really no excuse for not doing this examination at the time of initial patient contact. With the routine 20-cm depth of insertion, the entire rectum and the distal 5 to 10 cm of the sigmoid colon can be examined, specifically looking for anorectal tears or hemorrhoids. If a primary physician misses the opportunity to locate vigorous bleeding from a hemorrhoid, the patient may be subjected to an additional series of unnecessary, invasive, expensive and possibly dangerous diagnostic procedures. The time to make the diagnosis of hemorrhoidal or traumatic rectal bleeding or to exclude distal bleeding is during the initial contact with a patient.

Fiberoptic Sigmoidoscopy

Flexible fiberoptic sigmoidoscopy has recently been available using equipment costing more than $2,000. The most popular models are those in the range of 35 to 60 cm in length. With flexible fiberoptics, the examination can be done with the patient in the left decubitus position. Thus, there is enhanced patient tolerance of the procedure, which ordinarily does not require any intravenously given sedation. Probably the main reason for the development of flexible sigmoidoscopic equipment is the disproportionate number of cases of colorectal malignant tumors in western societies that are found in the distal bowel. Nearly two thirds of colorectal cancers are within easy reach of the 60-cm flexible sigmoidoscope. We must remember, however, that 50% of colorectal neoplasms are within easy reach of the 20-cm examination done with the rigid proctoscope. The depth of insertion achieved by most examiners with the rigid proctoscope is about 20 cm; examination with a flexible 60-cm sigmoidoscope will usually advance to about 50 cm. One will indeed pick up a larger percentage of polypoid and sessile colonic neoplasms using the longer flexible instruments. The problem with the flexible sigmoidoscopic examination is that the initial start-up costs are about 50 times greater than those for rigid sigmoidoscopy and the fees charged are often two or three times those for rigid proctoscopy.

Barium Radiography

Let us now consider barium enema radiography. This procedure has been the standard diagnostic evaluation following proctoscopy in patients with hematochezia. This examination, however, is extremely difficult to do adequately in a patient who is having vigorous bleeding. In general, barium enema evaluation should *never* be used as an early diagnostic procedure in a patient who is vigorously bleeding. The presence of blood, mucus and stool in the colon prevents adequate mucosal coating with barium. Many of the lesions, in addition, are superficial mucosal (angiodysplasia or small polyps) and would not be detected even by the finest of barium enema examinations done in a meticulously cleaned colon. Probably the main reason for avoiding barium radiography in a patient who appears to be bleeding briskly is that the use of barium limits the ability to carry out subsequent angiographic contrast studies if necessary. There have, however, been dramatic advances in the contrast enema technique, particularly with the availability of air-contrast or double-contrast studies. This procedure is acceptable in patients with chronic, intermittent lower gastrointestinal tract bleeding after proctosigmoidoscopy has been done. It is important to stress that the standard of care around the world dictates that patients undergo barium enema evaluation only *after* thorough proctoscopic examination. It is unacceptable for patients to be subjected to a barium enema evaluation without having had prior proctosigmoidoscopic examination.

The most important reason for avoiding a single-contrast barium enema study in patients in hospital who have hematochezia may be its distinct insensitivity. The Tedesco series (Table 2) classified patients into two categories[1]: 173 patients had no abnormalities on a barium study and 85 patients had only colonic diverticula. Among the 173 who had normal findings on barium enema studies, 91 (or 53%) actually had another lesion picked up by subsequent pancolonoscopy. In those who had only colonic diverticula noted on barium enema evaluation, 42% had another lesion detected by pancolonoscopy. Overall, the false-negative rate for a single-contrast barium enema in patients with hemodynamically significant hematochezia and no abnormalities seen on proctoscopy was 50%! It really makes no sense, therefore, to do this examination in inpatients who have brisk hematochezia.

		Incidental lesions	7†
		Incomplete examination	1

*From Tedesco et al.[1]
†Incidental lesions are defined as polyps 5 mm or less in size.
‡Colonoscopy was successful on second attempt (one patient).

What about the air-contrast barium enema study for patients with hematochezia? There has been some resistance in the medical community to accepting the air-contrast barium enema study because it requires more time and attention on the part of radiologists. Patients must be better prepared in terms of cleansing the colon of debris because the examination uses a finely dispersed, micropulverized, high-density barium suspension, followed by a rectal insufflation of gas. Thoeni and Menuck studied the sensitivity of single- versus double-contrast barium radiography for polypoid lesions and compared the results with those of colonoscopy.[2] Their data for the sensitivity of single-contrast barium enema studies were similar to those of the Tedesco series. Whereas 45% of the polyps were missed by a single-contrast barium enema study, only 12% of the polyps were undetected by double-contrast barium enema.

Colonoscopy

Colonoscopy is very sensitive in picking up polypoid lesions, more sensitive than either single- or double-contrast radiography. The real problem with colonoscopy has been the difficulty in carrying out the procedure in bleeding patients who have not had rigorous colonic cleansing.[3-7]

The feasibility of colonoscopy as the first diagnostic procedure in patients without prior air-contrast barium enema studies has been studied in 176 patients, 111 of them having had a prior barium enema test.[8,9] Of these patients, 60% underwent air-contrast barium enema evaluation as their first diagnostic procedure, followed by the pancolonoscopy. Once again, using this approach, only 58% of the polyps, two thirds of the cancers and 40% of the cases of colitis were actually detected by double-contrast barium radiography. These patients then had pancolonoscopy, polyps were removed by loop cautery and other lesions were determined. The investigators then prospectively studied 65 other patients who had hematochezia, using colonoscopy as the first procedure. In these patients, the colonoscopists did not have a "road map" to tell them where to look for the polyps or where to look for abnormal mucosa. In these 65 patients, 67 lesions were detected. Following discharge from the hospital, the patients underwent follow-up air-contrast barium enema studies. No additional polypoid lesions and no other mass lesions were noted by follow-up double-contrast radiography. Colonoscopy is thus feasible and accurate without prior barium studies.

There are only two studies in the literature, both in abstract form, that examined the utility, the feasibility and the yield of early colonoscopy as the first diagnostic procedure in patients with brisk hematochezia.[10,11] The studies were by Forde at Columbia-Presbyterian Hospital in New York and Jensen and colleagues at the University of California, Los Angeles. In their combined series of 65 patients, taking the strategy of preparing the patients emergently overnight and doing the colonoscopy in the morning after admission, the number of patients who had no lesions detected dropped from the 30% in the Tedesco series to 15% in the Forde-Jensen

data. In 12% of the patients who were admitted with hypovolemia-associated hematochezia (all of whom had negative nasogastric tube aspirates), 12% were ultimately found to be bleeding from an upper gastrointestinal tract source! When these 65 patients had colonoscopy emergently, the single most common identifiable cause of the hematochezia in these patients was angiodysplasia—25% of total, a considerably higher frequency than the 6.6% in the Tedesco series. Colonic diverticular hemorrhage decreased in frequency from 19% to 14%.

Bowel preparation for colonoscopy. One of the major advances in the approach to patients with hematochezia and a procedure that is now available in almost all hospitals is the use of oral electrolyte solutions to prepare patients.[3-7] We recommend this approach very strongly in preparing patients for emergent colonoscopy. The substance is called GoLYTELY and it is an orally given colonic lavage solution that is available commercially (Table 3). The electrolyte concentration and osmolarity are nearly identical to ileal effluent. The main advantage of this mixture compared with Ringer's lactate solution or saline is that sulfate, the major osmotically active ion in GoLYTELY, is nonabsorbable, therefore retaining the sodium and potassium in the lumen. The major osmotically active substance is polyethylene glycol, a nonmetabolizable substance.[3] Because most patients with hematochezia are older patients, considerable concern was initially raised over administering 4 to 5 liters of an electrolyte solution to elderly patients in preparation for colonoscopy. The safety and the efficacy of this particular mixture have been validated. DiPalma at Wilford Hall Air Force Hospital in San Antonio randomly selected patients to receive clear liquids, magnesium citrate and enemas; a low-residue diet; a normal diet with a rigorous irritant and saline cathartic, or a normal diet up until the midnight before the colonoscopic evaluation and then 5 liters of GoLYTELY given orally with 10 mg of metoclopramide hydrochloride orally (Table 4).[6] In patients given GoLYTELY, the average weight loss was only .45 kg (1 lb), compared with the 1 to 2 kg (3 to 5 lb) that most patients lost with the more rigorous irritant cathartic preparation (Table 5). There were no significant alterations in serum sodium, potassium or bicarbonate values when using 5 liters of oral GoLYTELY solution. Moreover, comparing the irritant cathartic-treated patients with those given GoLYTELY, breath hydrogen and methane levels dropped precipitously in both groups of patients, documenting adequate evacuation of flammable colonic gases.[6] With 5 liters of GoLYTELY, 92% of the patients were adequately prepared for colonoscopy compared with lesser percentages of patients with the standard colonic preparations. There was some abdominal fullness but an enhanced willingness to repeat the GoLYTELY oral preparation when compared with standard evacuation protocol.[5]

Angiography and Technetium Scintigraphy

Angiography and nuclear scans have valuable roles in evaluating patients who have hematochezia.[12-14] The greatest difficulty encountered with angiography and technetium scintigraphy is the insensitivity in patients with modest hematochezia. The published sensitivity for angiography is 0.5 ml per minute, or detection of as little as 30 ml per hour of blood loss. In our experience, unless patients are bleeding about one unit of blood per hour, an angiogram is unlikely to be abnormal. Because about 10% to 15% of the bleeding lesions in patients with vigorous hematochezia are from the upper gastrointestinal tract, celiac artery angiography must be done in bleeding patients with normal inferior and superior mesenteric angiograms. Tolazoline hydrochloride, a vasodilator,

may be administered intraarterially to better define bleeding lesions. Angiography rarely diagnoses the cause of the hematochezia, but does locate the site of hemorrhage.[12]

Technetium scintigraphy, now available in most hospitals, is done by labeling a patient's own erythrocytes in vitro or in vivo with technetium Tc 99m pertechnetate. The procedure that we use at San Francisco General Hospital is to give an injection first with pyrophosphate and then with technetium pertechnetate, which binds to the pyrophosphate. The patient's own erythrocytes are therefore labeled and the abdomen may be scanned for as long as 20 hours (Figure 1). The published sensitivity is 0.05 ml per minute, or about ten times that of angiography. In general, if patients are bleeding one unit every two to four hours, technetium scintigraphy is likely to be abnormal. Scanning must be done frequently to avoid misinterpretations.[14] In some instances, proximal lesions will bleed intermittently and, with rapid intestinal transit, the radionuclide will localize in the distal bowel, giving the erroneous impression that the bleeding site was distal. A similar problem occurs with distal colonic bleeding sources in which blood backwash can occur, giving the erroneous impression on scan that the bleeding site is from the more proximal colon. In many centers, the technetium scintiscans are required studies before doing angiography. With nuclear scintigraphy, information is available regarding the site of hemorrhage, but again not the cause.

Suggested Approach to Patients Who Have Hematochezia

Taking these new procedures into consideration, what recommendations can be made in evaluating patients with hematochezia? (Figure 2). First of all, one must clearly document

that there is hematochezia and that bleeding is not from the vagina or from the urethra. Anoscopy and digital and sigmoidoscopic examinations are essential in every bleeding patient at the time of the first visit. Because about 10% to 15% of patients with hemodynamically significant hematochezia are actually bleeding from the upper gastrointestinal tract, one must look very carefully for this possibility.

A nasogastric tube lavage is mandatory in all patients with vigorous hematochezia. If there is any evidence of fresh blood or "coffee-grounds" blood on lavage, endoscopy must be done following sigmoidoscopy. If following vigorous lavage there is no blood but also no bile obtained, the lavage is not adequately sampling the contents of the duodenum. A posterior duodenal bulbar ulcer cannot be excluded by this negative lavage. If the patient is hypotensive, is briskly bleeding, has active bowel sounds or has a history of dyspepsia or confirmed peptic ulcer disease, endoscopy should be part of the initial evaluation of patients with hematochezia who have positive or equivocal results on gastric aspirate. If the results of sigmoidoscopy are truly normal, the physician must reevaluate the patient for the next diagnostic procedure, based on the estimated briskness of the hemorrhage. If hemorrhage is judged to be more than one unit every one or two hours, then an angiogram is likely to be abnormal and it should be the next diagnostic procedure. If bleeding is intermittent with a transfusion requirement of only one unit every two to four hours, a technetium scintiscan can and should be done with frequent scanning intervals. If, however, there is no active bleeding after initial stabilization, the patient should be given GoLYTELY lavage solution and colonoscopic evaluation done within a reasonable period of time. Overnight lavage preparation is acceptable, and the examination can be done within a day of admission for those patients who cease bleeding once they have been admitted to hospital.

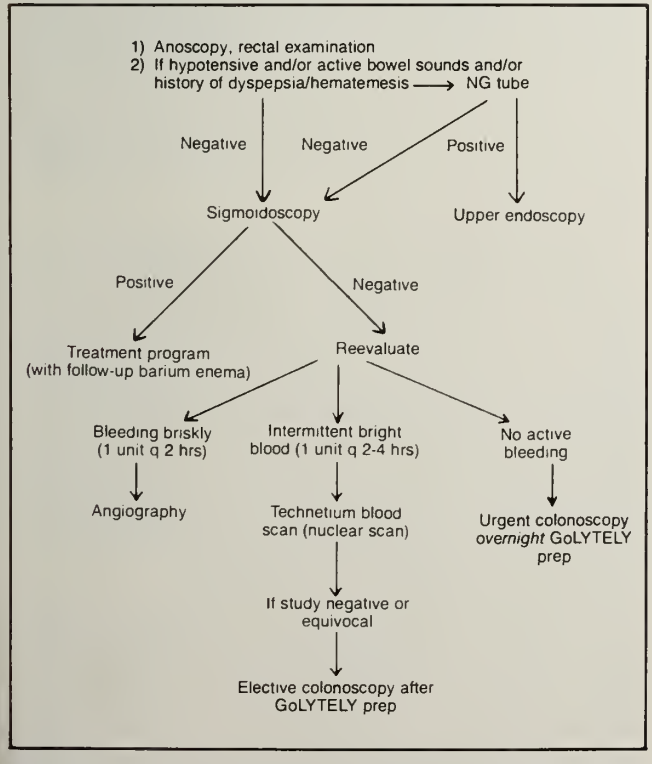

Figure 2.—Suggested approach to patients admitted to hospital with hematochezia. Nasogastric (NG) tube lavage and sigmoidoscopy must precede additional tests.

Diverticular Hemorrhage

I would like now to turn to two specific causes of hematochezia, the two most common identifiable causes of hematochezia when proctoscopy shows no abnormalities. The first is colonic diverticular hemorrhage. Diverticulosis is pervasive in western societies and 50% of persons older than 50 years will be found on routine barium enema evaluation to have colonic diverticula. Diverticula are associated with low-residue diets in animal species that have teniae coli—that is, longitudinal smooth muscle of the colon grouped into bands of musculature. Colonic diverticula in humans always develop on the mesenteric side of the two antimesenteric teniae.[15] The outpouchings of colonic mucosa develop through obliquely arranged tissue septa in circular smooth muscle. As a diverticulum protrudes, it carries with it on its dome a subtended, perforating, mesenteric arteriole that perfuses the mucosa and the submucosa of the adjacent bowel (Figure 3).

The pathophysiologic sequence for the development of diverticular hemorrhage is poorly understood.[15] Pathologically, it appears that there are eccentric intimal changes and finally eccentric vessel rupture (Figure 4). Clinically, colonic diverticular hemorrhage never occurs together with diverticulitis. Thus, most patients with diverticular hemorrhage usually have no symptoms of diverticulitis and may have little history of colonic dysfunction. Often the first manifestation of diverticular disease in many patients is brisk hemorrhage. Moreover, although 85% to 90% of colonic diverticula are

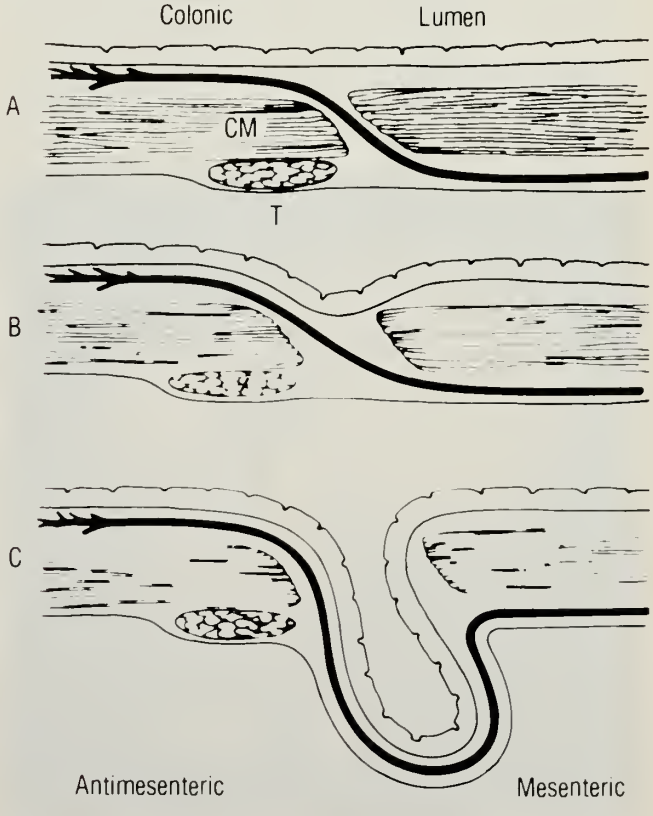

Figure 3.—Development of a colonic diverticulum. The outpouching of colonic mucosa (**CM**) through a tissue (**T**) septum carries with it a mesenteric arteriole. (Reprinted with permission from Meyers et al.[15])

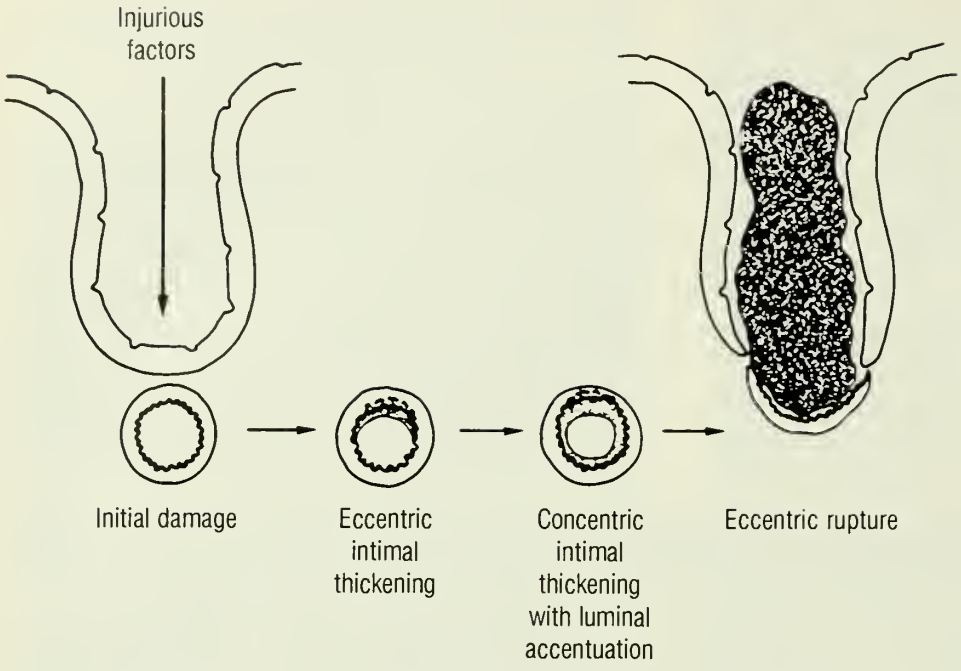

Figure 4.—Suggested sequence of diverticular hemorrhage. Hemorrhage rarely develops during the course of clinical diverticulitis. (Reprinted with permission from Meyers et al.[15])

located in the descending or sigmoid colon (where diverticulitis commonly occurs), more than 50% of cases of colonic diverticular hemorrhage are from the ascending colon or the cecum.[16]

Angiography will accurately pinpoint a site of brisk diverticular hemorrhage, but may not determine the cause of the colonic bleed. There have been considerable advances in the management of patients with diverticular hemorrhage using angiographic techniques.[13,17-19] With angiographic administration, it is possible to control the hemorrhage in the vast majority of patients with either administration of vasopressin alone or by occluding the bleeding vessel with embolic material. In primates, there is a profound decrease in mesenteric artery flow rates with angiographically administered vasopressin. The optimal dose in primates appears to be 0.005 units per kg of body weight per minute or about 0.35 units per minute of continuous, intraarterial infusion in a 70-kg (154-lb) person.[17] Unfortunately, at this dose range when vasopressin is given intraarterially, there is still substantial systemic toxicity. Arterially administered vasopressin at this dose will produce nearly a 25% decrease in cardiac output and sizable increases in peripheral vascular resistance and blood pressure. Nonetheless, angiographic vasopressin infusion does control colonic hemorrhage.[18,19] In addition, embolization using autogenous clot or other agents can arrest hemorrhage from colonic diverticula.[18,19] There are unfortunately no controlled trials of angiographic embolization procedures in which patients were randomly selected for either an operation or embolization. Further studies are desperately needed.

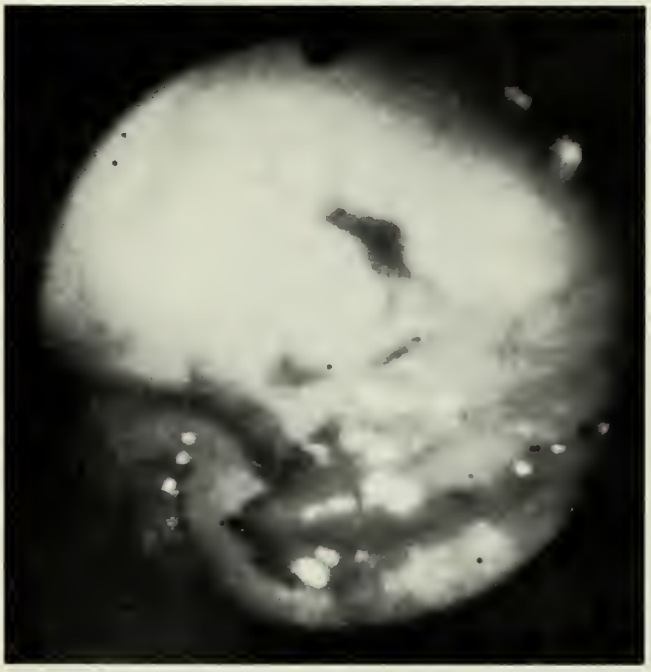

Figure 5.—Colonoscopic picture of cecal angiodysplasia. A central arteriole gives off radiating smaller vessels.

Colonic Angiodysplasia

Angiodysplastic lesions of the colon have been noted with increasing frequency, particularly in elderly patients, many of whom have severe underlying cardiopulmonary disease.[20-24] Many of these lesions are small spiderlike telangiectasias (Figure 5). Some of them actually assume an angiomatous appearance with large, almost polypoid, prominences. Histopathologically, angiodysplasia consists of dilated submucosal arteries, capillaries and veins. These lesions look similar to the spider angiomata that are noted on the chests of patients with cirrhosis.[20] Unfortunately, these colonic lesions are extremely thin-walled and precariously located just beneath the overlying columnar epithelium of the bowel.

In addition to the angiographic embolization techniques that have been popular now for the past ten years, these lesions have been successfully treated by a variety of coagulation procedures. Colonoscopic argon laser coagulation has been used in three to four different centers, including ours at San Francisco General Hospital.[23,24] The blue-green light of the argon laser is preferentially absorbed by the bright red of the angiodysplastic lesions. Coagulation depth with the argon

laser is only 2 mm, enhancing its safety in the thin-walled colon. The colonoscope is first passed to locate the abnormal area. Through the biopsy channel of the colonoscope, a polyethylene catheter containing a 400-micron quartz fiber is passed to transmit the blue-green laser light. A two-stage foot switch allows the operator to first aim at the target, then apply full treatment power. A white coagulum is produced. The most important change that occurs is not, however, the initial coagulation of the vessel but rather the subsequent development of an intense fibrotic reaction around the coagulated vessel. A localized barrier of dense fibrous tissue is thus developed between the overlying epithelium and the underlying vascular network. There are two studies in the literature, both in abstract form: Bowers and Dickson at Salt Lake City studied patients with angiodysplasia in the bowel treated with the argon laser. There was a decrease in both bleeding episodes and transfusion requirements in their series.[23] Jensen and associates likewise found a significant rise in the mean hematocrit over a 14-month period following argon laser endoscopy treatment.[24] In our own experience with nearly 40 patients with colonic angiodysplasia treated with the argon laser, nearly 80% have had no further bleeding.

In summary, there have been very dramatic and substantial advances in our approach to patients with hematochezia. Several exciting new treatment modalities have been recently developed. The evaluation of the patient with hematochezia requires a conscientious approach based on the estimated briskness of the hemorrhage.

Important Advances in Clinical Medicine

Internal Medicine

The Scientific Board of the California Medical Association presents the following inventory of items of progress in internal medicine. Each item, in the judgment of a panel of knowledgeable physicians, has recently become reasonably firmly established, both as to scientific fact and important clinical significance. The items are presented in simple epitome and an authoritative reference, both to the item itself and to the subject as a whole, is generally given for those who may be unfamiliar with a particular item. The purpose is to assist busy practitioners, students, research workers or scholars to stay abreast of these items of progress in internal medicine that have recently achieved a substantial degree of authoritative acceptance, whether in their own field of special interest or another.

The items of progress listed below were selected by the Advisory Panel to the Section on Internal Medicine of the California Medical Association and the summaries were prepared under its direction.

Intraarterial Chemotherapy

COLORECTAL CANCER affects 138,000 new patients and is responsible for approximately 60,000 deaths each year in the United States alone. Most patients who die of colorectal carcinoma have liver metastases, and for many the liver is the only clinical site of metastatic tumor. Chemotherapy for patients with metastatic disease consists of the fluorinated pyrimidines 5-fluorouracil (5-FU) and fluorodeoxyuridine (FUDR, or floxuridine). While 5-FU and floxuridine produce objective response rates of about 20% when given intravenously, neither has been proved to provide a survival advantage over no treatment.

A number of factors predict that 5-FU or floxuridine given via the hepatic artery may be superior to intravenous delivery in patients with liver-only metastasis from colorectal carcinoma. The blood supply of hepatic metastasis is primarily via the hepatic artery, whereas a normal liver receives a dual blood supply from the hepatic artery and portal vein. Thus, administering 5-FU or floxuridine into the hepatic artery exposes hepatic metastasis to a higher concentration of drug than normal liver tissue. Pharmacologic properties of 5-FU and floxuridine that may make hepatic artery therapy more effective include a favorable dose-response curve and high rates of first-pass hepatic extraction (80% and 95%, respectively), thus minimizing systemic toxicity. The cell-cycle phase-specific activity of 5-FU and floxuridine predicts increased cytotoxicity with long-term drug use such as is achievable with continuous infusion. The recent development of a reliable, implantable, continuous infusion pump has made hepatic artery infusion chemotherapy practicable. For these reasons, hepatic artery infusions, usually with floxuridine, have become an active area of clinical investigation.

The reported series of colorectal cancer patients treated with hepatic artery infusion have either been uncontrolled or historically controlled and are difficult to assess because they use a broad range of methods and criteria to measure response. Computed tomography, especially when done with volumetrics, is the single most objective and reliable index of disease response or progression. Radionuclide liver scans are reproducible but difficult to quantify in determining response. Although physical examination, liver enzymes and carcinoembryonic antigen levels are all unreliable methods of measuring the response of colorectal cancer metastatic to the liver, they have been used in many studies as indicators of disease response. Despite these frequently inexact methods of assessing response, the available studies of hepatic artery infusion of floxuridine have found impressive response rates ranging from 29% to 88%. In addition, some of these studies report superior durations of survival when compared with historical control groups. Whether these improved rates of response and survival are the result of variations in the tumor burden at the initiation of therapy, the methods of assessing response, the use of inappropriate control groups or of the efficacy of treatment is uncertain.

Hepatic artery infusion of floxuridine is associated with significant toxic effects, especially biliary sclerosis, which occurs in most patients. Recent evidence suggests that the "chemical hepatitis" reported previously may in fact have been biliary sclerosis. This is a serious toxic effect and has been documented by cholangiography, liver biopsy and at postmortem examination. It is heralded by elevation of the alkaline phosphatase level, and a doubling of the alkaline phosphatase level requires at least delaying further administration of the drug until the levels return to normal, with attenuation of further doses. The anatomic changes of biliary sclerosis are presumably not reversible and may contribute to drug-related mortality, although the associated elevations in alkaline phosphatase and bilirubin levels may resolve with the early withdrawal of therapy.

Gastric and duodenal inflammation and ulceration and cholecystitis are other complications of hepatic artery infusion of floxuridine. These complications appear to be related to the incidental perfusion of the involved organs by floxuridine. The frequency of the gastric and duodenal complications can be minimized at the time of pump implantation by ligating the gastroduodenal artery and collaterals that arise distal to the point of cannulation of the hepatic artery. Most investigators recommend routine cholecystectomy at the time of placement of the infusion pump to prevent the development of drug-induced cholecystitis.

No prospectively randomized studies comparing the efficacy and toxicity of intravenous with intraarterial administration of 5-FU or floxuridine have yet been completed. Appropriately designed, prospectively stratified, randomized trials comparing intravenous administration with hepatic artery infusion of chemotherapy for colorectal carcinoma metastatic to the liver only are in progress in the Northern California Oncology Group (headquarters in Palo Alto) and at the Memorial Sloan-Kettering Cancer Center (New York). Definitive conclusions regarding the precise role of hepatic arterial infusion chemotherapy must await the completion of these studies.

The Routine Preoperative Chest X-ray Study

ACCORDING TO THE REPORT of a World Health Organization (WHO) Scientific Group, "There are some excellent studies on the futility of preoperative chest radiography," a conclusion that was reached after a comprehensive study of the relevant international medical literature. This opinion is endorsed by the Food and Drug Administration, the US Bureau of Radiological Health and most of the American specialist colleges and societies. If the results of a clinical examination are normal, no preoperative chest x-ray film is needed at any age for any surgical procedure. Moreover, even when there are clinical chest symptoms, there is little advantage to be gained in most cases because clinical judgment will decide the choice of anesthesia with as much accuracy as a chest x-ray study. Nor will postoperative management be affected by information gained from a preoperative chest film, which is not only not cost-effective but increases the radiation given both to an individual patient and to the population. Indeed, it is time that the routine chest film cease to be part of a routine physical examination, preoperatively or otherwise; the only exception may be in populations wherein chest disease is known to be prevalent.

The WHO Scientific Group on the Indications for and Limitations of Major X-Ray Diagnostic Investigations concluded that

> provided a careful clinical examination is made and there is no clinical evidence of chest disease, there is no indication for preoperative chest radiology. If the clinical examination discloses an abnormality, this in itself is not necessarily an indication for radiography. Such cases must be judged on their merits.

Fine-Needle Aspiration Biopsy of Thyroid

THYROID NODULES are common and about 4% or 40,000 per million persons in the United States have nodular goiters. Thyroid cancer, however, is rare: about 40 cases per million persons. Thus, great selectivity is necessary in deciding which nodules are likely to be malignant and to require aggressive surgical management.

Fine-needle aspiration biopsy of the thyroid has largely solved this dilemma. Introduced by Soderstrom in 1952, it has been used widely in Sweden, Europe and Japan. Only in the past ten years, however, with the development of a cadre of trained cytologists, has fine-needle aspiration biopsy been widely used in the United States.

Fine-needle aspiration biopsy of the thyroid is a simple office procedure, nontraumatic, acceptable to patients and easily repeated if necessary. If the aspirate is diluted with blood, or not enough thyroid tissue is obtained, it must be repeated. Other than an occasional tiny hematoma at the site of aspiration, there have been no complications. There has been no spread of cancer with this technique.

A physician will usually receive one of three reports from the cytologist: (1) clearly malignant, (2) clearly benign or (3) follicular neoplasm or suspicious for neoplasm.

Papillary, medullary, anaplastic and metastatic neoplasms are easily diagnosed and, if present, require surgical confirmation and appropriate therapy. Clearly benign lesions include involutionary nodules, benign thyroid nodules, chronic lymphocytic thyroiditis (Hashimoto's thyroiditis), subacute thyroiditis and multinodular goiter. Patients with these lesions are usually treated with levothyroxine to suppress thyroid-stimulating hormone and growth. Follicular neoplasms are usually benign (about 85%) but occasionally malignant (15%). If the lesion is large (more than 2 cm), firm or has shown recent growth, it should be surgically removed. If it is small and soft, the patient can be given a trial of thyroxine therapy for three to six months. If the lesion fails to regress or grows, then it should be removed. Cysts of the thyroid can

easily be evacuated by this technique and they are rarely malignant (less than 5%). Malignant lesions will usually recur, with bloody fluid and evidence of internal echos on ultrasound scan. If thyroid cysts do recur after two or three aspirations, they probably should be surgically removed.

False-positive results—that is, a diagnosis of cancer in a benign lesion—occur in about 4% of aspirations, and false-negatives—that is, a diagnosis of a benign lesion in the presence of malignancy—in about the same percentage. Thus, the method is both sensitive and specific. Note that fine-needle aspiration biopsy can be used in the diagnosis of other neck masses, such as metastatic cancer or Hodgkin's disease.

Fine-needle aspiration biopsy of the thyroid is probably the most important advance in the management of thyroid nodules in the past decade. It has enabled physicians to avoid delay in the diagnosis of thyroid malignancy and to avoid an unnecessary operation for benign thyroid lesions. As the initial screening test, it will reduce by half the cost of evaluating a thyroid nodule.

New Criteria for the Diagnosis of Alzheimer's Disease

WITH THE INCREASED publicity concerning Alzheimer's disease, the development of state initiatives for diagnosing and treating cases of Alzheimer's and the appearance on the horizon of a number of experimental therapies, the accurate diagnosis of this disorder becomes important. Unfortunately, there is no biochemical or radiographic marker upon which a clinician can rely. In 1980, the American Psychiatric Association in the third edition of its *Diagnostic and Statistical Manual* (DSM-III) proposed criteria that have been widely accepted for the clinical diagnosis of Alzheimer's disease. However, these criteria have been found to apply to only about half of the Alzheimer patients because the disease presents in a greater variety of ways than first believed. Thus, under DSM-III criteria, a patient with Alzheimer's disease was required to have impairment not only of memory, but of at least one other area of cognition; the course was described as having an insidious onset with a steady progression, and, most important, other neurologic or systemic disorders that can produce dementia had to be excluded.

In reality, it has been found that in some patients Alzheimer's disease may begin primarily as a memory, language or constructional deficit that may progress for several years before becoming more generalized. The course is always one of deterioration, but in some patients it may be interrupted by plateaus lasting for several years.

Particularly in older patients with Alzheimer's disease, the coincidence of an Alzheimer process with a single stroke, with thyroid disturbance, vitamin B_{12} deficiency and so forth, may occur. To account for these deviations and to provide a wider umbrella for physicians, a work group under the auspices of the Department of Health and Human Services Task Force in Alzheimer's Disease arrived at the following recommendations:

1. A diagnosis of *definite* Alzheimer's disease requires clinical criteria for probable Alzheimer's disease and histopathologic evidence obtained from a biopsy or autopsy.
2. The criteria for a clinical diagnosis of *probable* Alzheimer's disease are similar to those of the original DSM-III and include the following:
   - There must be a dementia established by clinical examination and documented by a mental state test that includes deficits in two or more areas of cognition;
   - There should be progressive worsening of memory and other cognitive functions;
   - No disturbances of consciousness;
   - The absence of systemic disorders or other brain diseases that, among themselves, could account for progressive deficits.

This diagnosis of probable Alzheimer's disease is similar to that originally described in DSM-III.

Critical to the diagnosis of dementia is the documentation of the cognitive deficit by the use of mental state tests such as the Mini-Mental Test or a similar examination. The importance of tests of mental state is emphasized because patients with dementia early in the course of their disorder may maintain good social conversation and may not be obviously demented during routine history taking. Laboratory features consistent with a diagnosis of probable Alzheimer's disease include a computed tomographic scan normal for age or with evidence of cerebral atrophy, a normal electroencephalogram or one with increased slow-wave activity and normal findings on a lumbar puncture. Often there is a family history of similar disorders. As the disease progresses, there is impairment of activities of daily living and altered patterns of behavior. There may be associated symptoms of depression and decreased cognizance, delusions, hallucination, verbal or physical outbursts, sexual disorders and weight loss. Usually there are no focal neurologic findings such as hemiparesis, sensory loss, visual field deficits or incoordination early in the course of Alzheimer's disease.

A third category of diagnosis is that of *possible* Alzheimer's disease. This category includes patients who have a progressive dementia but have either a variation in the onset, presentation or clinical course or a systemic or brain disorder that is enough to produce dementia, but it is not considered to be the cause of dementia because, when treated, the dementia continues to progress. Among the variations of onset is a subgroup of patients who present with a progressive deterioration in a single area of cognitive function, such as aphasia, apraxia or agnosia, or a pure memory deficit for several years before the development of a more generalized disorder. Such patients, however, must be investigated for the possibility of focal neurologic disease.

These criteria emphasize both the normal history and progression seen in patients with Alzheimer's disease and the continued need to exclude other disorders that may produce a

dementia syndrome. Among the more common disorders that must be excluded are multi-infarct dementia, bipolar depressive disorders and drug intoxications. Other disorders that may occur and produce dementia include thyroid disease, pernicious anemia, neurosyphilis, Creutzfeldt-Jakob disease, subdural hematoma, normal pressure hydrocephalus, Huntington's disease and a brain tumor. The workup of a patient with Alzheimer's disease requires an accurate medical history, neurologic, psychiatric and clinical examinations and laboratory studies to exclude these other diagnoses. Widespread adoption of these recommended criteria for the clinical diagnosis of Alzheimer's disease would lead to improved communication among the physicians caring for patients with this devastating disorder.

Clinical Use of Platelet-Suppressant Drugs

ASPIRIN, by inhibiting cyclooxygenase, blocks the formation by the platelet of thromboxane A_2, the most powerful natural potentiator of platelet aggregation. The effect is prolonged, probably for the life span of the platelet, and can be shown in vivo by a prolonged bleeding time. As cyclooxygenase is required also by endothelial cells to form prostacyclin, which inhibits platelet aggregation, there has been some concern that the overall effect of aspirin might not be to reduce arterial thromboembolism. There have been many clinical trials with aspirin and other drugs that interfere with platelet function and analysis of these as a group allows us to make some clinical recommendations.

Aspirin can reduce (by about 5% in the first year) the risk of sudden death and of myocardial infarction in persons with a high risk of these incidents, namely, those who have had a recent transient ischemic attack or myocardial infarction or who have unstable angina. In two studies the frequency of coronary artery bypass graft occlusion was reduced by aspirin therapy initiated shortly before or immediately after an operation. There is also evidence that aspirin reduces the risk of stroke and sudden death following a transient ischemic attack and that it is effective in preventing thromboembolic complications in patients with essential thrombocythemia and polycythemia and the occlusion of arteriovenous shunts. The studies as a whole show a significant reduction in morbidity for men only because the number of women studied was too small, but there is no known pharmacologic or physiologic reason why the effect should be sex-dependent. The benefit is greater the earlier the aspirin therapy is started and is apparent within the dose range of 100 to 1,000 mg a day. Aspirin is contraindicated in those with other acquired or inherited hemostatic deficiencies, in patients with significant dyspepsia or with previous gastrointestinal bleeding; these considerations will exclude about 10% of otherwise suitable patients.

Although a beneficial trend has been noted in the trials of sulfinpyrazone in patients with transient ischemic attacks, the results are not statistically significant, and neither this drug nor dipyridamole can yet be recommended for routine use either alone or combined with aspirin. There is no indication for using aspirin to prevent embolization from prosthetic heart valves, for which anticoagulants remain the first line of therapy, with sulfinpyrazone giving added benefit.

Many questions remain to be answered, including the most effective dose of aspirin, the duration of treatment, the role of combination therapy with other platelet-function-altering drugs and the evaluation of new drugs, particularly ticlopidine hydrochloride, pentoxifylline and ketanserin. Clinical trials designed to study these matters are in progress and their results are eagerly awaited.

Adjuvant Chemotherapy for Breast Cancer

STAGE I (T_1,N_0,M_0) and stage II (T_1,N_1,M_0, T_2N_{0-1},M_0) breast cancers are potentially curable with local-regional therapy. The risk of recurrence, usually at distant sites, after such therapy is also known. The cause of recurrent disease is microscopic metastatic tumor already present but not identifiable at the time of the initial operation. Given these conditions, administering systemic antitumor therapy as an additional (adjuvant) treatment to eradicate residual tumor, after definitive local-regional therapy, is a rational approach.

Over the past 15 years, dozens of adjuvant therapy trials in breast cancer have been devised and patient accession completed, and the data examined and reexamined for statistical significance and clinical implications. The adjuvant treatments have ranged from two- to five-day courses of a single chemotherapy agent given immediately after surgical treatment, to multidrug chemohormonal therapy combinations given for two years. The early trials concentrated on women with involved axillary nodes (N_1) who were at high risk for recurrence. More recently, node-negative trials have also been initiated. Data analysis has been exhaustive. Updates have been frequently presented and regularly published. Prognostic subgroups have been studied—premenopausal and postmenopausal women, patients with one to three positive nodes versus those with four or more nodes involved, or four to ten nodes versus more than ten nodes. Explanations for the various results seen in different subgroups abound.

Two important benefits may accrue from adjuvant chemotherapy: Improved overall survival is the primary possible benefit of adjuvant treatment and is the one ultimately sought.

However, prolonged relapse-free survival may also be worthwhile. Enhanced relapse-free survival and even improved overall survival must be weighed against possible toxicity, monetary costs and effect on life-style in finally deciding the value of adjuvant therapy as standard care. Therefore, until long-term data are available and a beneficial impact is clear, adjuvant programs should remain within the realm of experimental therapy.

In premenopausal women with metastasis to nodes, numerous studies show significantly prolonged relapse-free survival and some show an overall survival benefit after adjuvant chemotherapy. While single-drug trials show such benefits in some premenopausal subsets, the multidrug adjuvant programs of Bonadonna and co-workers with CMF (cyclophosphamide, methotrexate and 5-fluorouracil), now reported with a ten-year median follow-up, appear broadly efficacious among premenopausal patients. The optimal duration of treatment is under study. In one controlled trial, 6 months of CMF therapy were as good as 12 months. Even shorter programs of more intense therapy may eventually be found to be equally or more useful. Therefore, while giving multidrug adjuvant chemotherapy to node-positive, premenopausal women has achieved the status of "conventional" or "standard" treatment, research trials to further define optimal drugs and treatment schedules are in order. These new trials will not include a "no-treatment" control group.

Data on the efficacy of adjuvant therapy using drugs, hormones or a combination of both for postmenopausal women with involved axillary nodes (N_1) are widely available. A few studies have shown clear benefit, with enhanced relapse-free and overall survival. Others show enhanced relapse-free survival without concomitant overall survival advantage. Still others—slightly more than half of all reported—show no benefit on either count. Some investigators have emphasized the need to give full-dose adjuvant chemotherapy to postmenopausal women to obtain beneficial results. Others, concerned with the toxicity of adjuvant chemotherapy in older patients, have turned to trials of adjuvant hormonal therapies.

The available data stimulate controversy about the place of adjuvant therapy in the management of postmenopausal women with positive nodes. It seems inappropriate to present adjuvant multiagent chemotherapy as "standard" for postmenopausal women based on the evidence of clinical trials thus far. However, enough positive data are available to demand further evaluation of various adjuvant approaches using the mechanism of well-designed, large-scale, cooperative clinical trials. Questions of dose, duration, amount, nature and timing of treatment all warrant investigation. Clinical trials evaluating such issues in node-positive postmenopausal women should ideally include a no-treatment control group, though this issue of study design is highly controversial in and of itself.

Adjuvant therapy for breast cancer has had an important, beneficial impact, especially in premenopausal women with metastasis to nodes. Clearly, however, we are far from having all the answers. Continued commitment among physicians to participate in well-designed trials that both ask important questions and offer the most advanced patient care is crucial. With the strong support of the medical community to continue careful adjuvant therapy trials in breast cancer, the uncertainties extant in the field today should give way to further positive directions over the next several years.

Cyclosporine—A Powerful New Immunosuppressant

CYCLOSPORINE IS A powerful immunosuppressive drug that has had a major impact on the success of organ transplantation since its introduction a few years ago. It has a unique cyclic endecapeptide structure, which inhibits T-cell activation, without directly affecting B cells, macrophages or any other branch of the immune responses. Unlike its predecessor, azathioprine, cyclosporine has not thus far proved toxic to rapidly proliferating cells such as bone marrow. A further advantage of cyclosporine therapy is the reduced or eliminated requirement for prolonged administration of high-dose corticosteroids, with a resultant improvement in the quality of life for transplant recipients. An unexpected benefit has been a shorter hospital stay and a reduction in the cost of transplantation by as much as 30%.

Cyclosporine use has improved the one-year survival rate of cadaveric renal allografts from 50% to as high as 85%. Similarly, the one-year survival rate of heart transplant recipients has increased from about 60% to 80%. The one-year survival rate of liver transplant recipients has almost doubled, to 70% for children and 50% for adults. Clinical heart and lung transplantation, which was never done successfully before cyclosporine, has now been carried out in more than 20 patients, with a number of long-term survivors. A survival advantage in pancreas and bone marrow transplant patients treated with cyclosporine has not been clearly shown, though it does lower the incidence and severity of graft-versus-host disease. Because of its powerful immunosuppressive properties, the use of cyclosporine is being considered in a number of diseases with purported immune mechanisms. A successful trial of cyclosporine in abolishing insulin requirements among patients with type I diabetes mellitus was recently reported.

Cyclosporine has a number of clinically mild side effects including hirsutism, gingival hyperplasia, nausea and elevated liver enzyme values. In rare cases, there is also central nervous system toxicity including ataxia, quadriparesis, changes in mental state and aseptic meningitis. The incidence of opportunistic infections is similar to that of azathioprine-treated patients, although their severity appears to be reduced. Lymphoproliferative malignant disorders initially ap-

peared to be increased among cyclosporine users but recent experience is reassuring. These B-cell tumors appear to follow reactivation of or infection with Epstein-Barr virus (EBV) and contain the Epstein-Barr nuclear antigen (EBNA) or portions of the EBV genome. These tumors may represent uncontrolled proliferation of virally transformed lymphocytes and respond temporarily to the antiviral agent acyclovir. Reducing or eliminating immunosuppression has also been followed by remission of tumor, albeit associated with graft rejection.

The most serious common side effect of cyclosporine is its nephrotoxicity. In as many as 80% of recipients a significant rise in the serum creatinine level occurs. This appears to involve both glomerular and tubular damage, and it is at least partly dose-dependent. Though renal insufficiency can often be minimized by reducing the dose or by switching the therapy to azathioprine, many patients will have irreversible renal damage and a few require dialysis. Cyclosporine nephrotoxicity is a problem in renal transplantation because it cannot be easily distinguished from graft rejection; it is especially worrisome in heart and liver transplant recipients, in whom reduction of immunosuppression and subsequent graft rejection may result in death. The renal lesion is accompanied by hypertension, which is often very difficult to control.

Cyclosporine has had a favorable impact on the field of organ transplantation, but its long-term utility may be limited or negated by its nephrotoxicity. Clinical studies are currently being done to define the precise role of cyclosporine in organ transplantation. Obviously, caution must be exerted in using this substance in any condition, including diabetes, where morbidity and mortality may be determined by renal function.

Non-A, Non-B Hepatitis

THE ABILITY TO diagnose hepatitis A, hepatitis B, δ-agent, cytomegalovirus and Epstein-Barr virus infections through specific serologic tests has uncovered a series of patients in whom syndromes develop that resemble viral hepatitis but serologic test results do not suggest the above illnesses. These patients have a condition currently known as non-A, non-B hepatitis, which is responsible for about 90% of cases of posttransfusion hepatitis and 25% of sporadic cases of hepatitis in the United States. Studies of outbreaks in communities or hospital facilities of many episodes of viral hepatitis in humans and chimpanzees and of repeated inoculations of chimpanzees and marmosets with infectious serum have established the existence of more than one agent responsible for this illness. At least one of the agents appears to be waterborne, spread by the fecal-oral route and does not lead to a carrier state. Current interest in discovering the etiology of non-A, non-B hepatitis is reflected by the many reports identifying agents possibly related to this illness. These include reverse transcriptase activity in plasma products and human serum specimens from cases of posttransfusion hepatitis, 27-nm viruslike particles in stool specimens of Nepalese patients with epidemic non-A, non-B hepatitis and marmosets infected with their serum, a putative antigen by immunocytochemical staining in the liver of a chimpanzee with acute non-A, non-B hepatitis and isolation of an 85- to 90-nm membrane-coated virus from chimpanzee liver cultures inoculated with serum from patients with posttransfusion hepatitis. Other investigators have repeatedly detected hepatitis B viral DNA and hepatitis B surface antigen by radioimmunoassay using monoclonal antibodies in non-A, non-B carrier livers or serum specimens. Whether non-A, non-B infection will eventually prove to be due to any of these agents is still open to independent confirmation of these findings.

Non-A, non-B hepatitis should be looked for in patients with sporadic or posttransfusion acute or chronic hepatitis in whom laboratory tests rule out the viral illness previously mentioned. Other conditions to investigate depend on the clinical setting and may include infections (δ-agent, herpes simplex, syphilis, toxoplasmosis, brucellosis, Q fever), metabolic disorders (Wilson's disease, hemachromatosis, fatty liver), biliary tract disease, hemodynamic insults to the liver, drug-induced liver disease and idiopathic chronic active hepatitis.

The clinical course of non-A, non-B hepatitis is variable and may depend on the nature of the responsible agent, the vehicle or route of administration and host factors not yet characterized. Although most cases of posttransfusion acute non-A, non-B hepatitis are clinically silent, this illness causes as many cases of fulminant hepatitis in the United States as does hepatitis B. Posttransfusion non-A, non-B hepatitis leads to serious chronic liver disease (chronic active hepatitis or cirrhosis) in as many as 60% of cases in some series. Primary hepatocellular carcinoma has been described in patients whose only risk factor appears to be posttransfusion non-A, non-B hepatitis.

It is unclear whether this illness can be prevented by administering immune globulin before or after exposure. In a trial of immune serum globulin (ISG) in 175 patients undergoing a cardiovascular surgical procedure, the incidence of posttransfusion hepatitis in treatment and control groups was the same. In a randomized, placebo-controlled trial of hepatitis B immune globulin (HBIG) and ISG in 279 cardiac operation patients, recipients of either globulin preparation had a lower incidence of icteric non-A, non-B hepatitis (1.1% versus 7.4%) and fewer patients progressed to chronic liver disease (0.5% versus 10%). In a similar trial of ISG in posttransfusion prophylaxis of 2,204 patients, ISG reduced the incidence of icteric hepatitis (0.8% versus 1.8%) but not anicteric cases (7.7% versus 6.9%). The biggest reduction in posttransfusion hepatitis in this study was achieved not by ISG treatment but by the use of noncommercial blood (2 cases in 775 recipients of volunteer blood, both in the ISG group). The results of these trials are not easily compared because the globulin preparations, source of blood transfused and recipi-

ents of blood products were different. The studies taken as a group, however, suggest that the exclusive use of volunteer blood may be the most useful measure to prevent posttransfusion hepatitis. Others have shown that serum alanine aminotransferase (ALT) or anti-hepatitis B core antibody (anti-HBc) testing of blood donors and rejection of blood units with elevated ALT or anti-HBc levels may decrease the incidence of posttransfusion hepatitis in recipients. Whether or not immune globulin administration or any other measure can reduce the incidence of hepatitis after transfusion of volunteer blood with normal ALT levels and absent anti-HBc remains to be proved. To date, blood banks have not adopted a policy of screening for these serologic markers epidemiologically associated with non-A, non-B hepatitis infectivity. A recent randomized, placebo-controlled trial of HBIG versus placebo in hemodialysis patients has shown prevention of non-A, non-B hepatitis during but not after administration of HBIG, suggesting that protection was passive and no active immunization occurred.

Treatment studies in this illness continue to be hampered by the lack of reliable diagnostic tests. An unknown number of cases of posttransfusion non-A, non-B hepatitis have been included in trials of corticosteroids in treating chronic active hepatitis. The proper management of chronic active non-A, non-B hepatitis may include a trial of prednisone if the illness is symptomatic, serum aminotransferase and globulin levels are moderately to greatly elevated and a liver biopsy specimen shows severe active liver disease. At Stanford University Medical Center we are currently enrolling patients in a pilot study of human leukocyte interferon for treating patients with posttransfusion non-A, non-B chronic active hepatitis.

Identifying the agent of non-A, non-B hepatitis and developing reliable diagnostic laboratory tests for its detection will allow rigorous reexamination of the data summarized above. A better understanding of the natural history and transmissibility of non-A, non-B hepatitis will then allow a rational approach to its treatment and prevention.

New Antibiotics

SEVERAL NEW ANTIBIOTICS entered into clinical practice in 1984 and the role of the third-generation cephalosporins was better defined. Although the latter antibiotics are costly, they have several advantages over first- or second-generation cephalosporins and a very competitive race has ensued between cefotaxime, moxalactam, ceftizoxime, ceftazidime and cefoperazone. These agents are frequently used in the empiric treatment of patients with infections like bacterial sepsis, bacillary meningitis or pneumonia before the cause is identified by laboratory studies. Physicians often substitute these compounds for aminoglycosides such as tobramycin and gentamicin to avoid nephrotoxicity. This is particularly the case in infections such as septicemia and community-acquired pneumonia in immunocompromised patients.

Another new antibiotic is a combination of clavulanic acid with ampicillin. The former compound binds β-lactamases of Gram-positive and Gram-negative bacteria, thus allowing ampicillin to penetrate bacterial cells before it is destroyed. Organisms frequently resistant to ampicillin such as *Staphylococcus aureus, Klebsiella* and other Gram-negative bacilli are now sensitive. This compound is taken orally and can be used in treating complicated outpatient infections. We are also looking with interest at a new class of antibiotics known as the quinolines (pyridonecarboxylic acid compounds) which are derived from nalidixic acid. Such agents include ciprofloxacin, norfloxacin and enoxacin and have a broad range of antibacterial activity against both Gram-positive and Gram-negative bacteria. The bottom line is that a physician who practices primarily in the outpatient arena will have several new compounds effective against complicated infections and that will shorten hospital stays.

The concept of diagnosis-related groups (DRGs) and its inherent logic that dictates reimbursing hospitals is also having an effect on antibiotic prescriptions. Hospitals are looking to their pharmacies to provide tighter guidelines for the use of antibiotics, as they often account for 20% to 30% of all pharmacy purchase costs. New ways are also being developed to treat morbid infections in the outpatient clinical area and thus decrease the duration of hospital stay for patients who have resolving infections such as osteomyelitis, abdominal abscess, pneumonia, empyema and even endocarditis. Infusion centers exist where patients can receive on a daily outpatient basis antibiotics via Hickman lines or catheters in peripheral veins with "heparin locks." Another approach is to employ nurses to visit the homes of patients to administer antibiotics daily. Antibiotic costs will probably gain in importance as a deciding factor in their use.

Calcium Channel Blockers

CALCIUM CHANNEL BLOCKING agents are important new drugs used in treating coronary and other cardiac diseases. The currently available drugs, diltiazem hydrochloride, nifedipine and verapamil, have been effective in treating coronary artery spasm, and their use in the management of angina and supraventricular arrhythmias has been well documented. The ability of these agents to prevent or relieve spasm theoret-

ically makes them ideal for use in treating other smooth muscle disorders. Although the three available drugs all inhibit the entrance of calcium into cells, they are different compounds and vary in their clinical effect. Nifedipine is a stronger peripheral vasodilator, verapamil causes more myocardial depression and diltiazem and verapamil affect the sinoatrial and atrioventricular nodes. Consideration of these factors is important in choosing which drug will be used, either alone or combined with other drugs such as β-blockers or nitrates.

Several clinical trials have shown the effectiveness of these drugs in treating systemic hypertension, often used as monotherapy. Nifedipine has been extensively studied and may be more beneficial due to its more potent peripheral vasodilating property, and it is very effective in managing cases of hypertensive crisis. Verapamil and diltiazem are also effective in treating hypertension and it is felt by some that they may be more suitable for long-term treatment because nifedipine is more likely to lead to reflex activation of the sympathetic nervous system.

The use of calcium channel blocking drugs in the treatment of pulmonary hypertension is encouraging. All three drugs have reduced pulmonary artery pressure and pulmonary vascular resistance in patients with primary pulmonary hypertension and some types of secondary pulmonary hypertension. However, the response to calcium entry blocking agents in patients with precapillary pulmonary hypertension is unpredictable and the drugs may sometimes produce deleterious effects.

Active clinical investigation is continuing in the use of calcium channel blockers for other conditions, including congestive heart failure, hypertrophic cardiomyopathy, myocardial preservation, bronchial asthma, Raynaud's phenomenon, migraine headache, cerebrovascular spasm, cerebral ischemia, premature labor and disorders of esophageal motility. Calcium channel blockers will likely be increasingly used in smooth muscle disorders, especially as new drugs become available that are more specific for certain types of smooth muscle.

The Protein C Anticoagulant Pathway and Thrombosis

PROTEINS C AND S are recently discovered vitamin K-dependent proteins that unlike the other vitamin K-dependent clotting factors—II, VII, IX and X—act as physiologic anticoagulants rather than procoagulants. Activated protein C inhibits coagulation by destroying activated factors V and VIII; protein S is an essential cofactor in the expression of protein C's anticoagulant activity. Protein C circulates in an inactive zymogen form and is activated by thrombin bound to an endothelial-cell surface protein, thrombomodulin. Activated protein C may also have a stimulatory effect on fibrinolysis. The protein C anticoagulant pathway thus provides a mechanism whereby formation of thrombin is accompanied by generation of anticoagulant and profibrinolytic activity, limiting fibrin formation to areas of local vascular damage.

Hereditary deficiencies of the protein C anticoagulant mechanism are associated with venous thromboembolic disease. Heterozygous protein C-deficient persons have about half the normal amount of protein C. Many but not all manifest recurrent episodes of thrombophlebitis, pulmonary embolism or both, beginning after the first decade of life, often associated with a precipitating event such as trauma or an operation. Administering heparin or warfarin is effective. Warfarin therapy reduces the levels of all vitamin K-dependent proteins, but protein C levels fall faster than levels of factors II, IX and X. Therefore initiating warfarin therapy, especially with loading doses, may create a brief period of increased vulnerability to thrombosis, including the rare syndrome of dermal thrombosis with necrosis ("warfarin skin necrosis"). Such complications can be avoided by continuing a regimen of heparin for several days, until full oral anticoagulation has occurred.

Homozygous protein C deficiency has been described in several newborns, who have little or no detectable protein C and who show dramatic, life-threatening thrombotic complications, including purpura fulminans, a necrotic dermal thrombotic lesion closely resembling warfarin skin necrosis. Constant protein C repletion with prothrombin complex concentrate is the only effective therapy so far described; however, this therapy is associated with a risk of transmitting hepatitis. Acquired deficiency of protein C is seen in cases of disseminated intravascular coagulation, liver disease, vitamin K deficiency and warfarin therapy; the clinical consequences of such deficiency states are not well established.

A diagnosis of protein C deficiency is best made with one of the recently described functional assays, as normal levels of a functionally defective molecule will not be detected by antigenic assays. Its diagnosis in a patient receiving warfarin requires finding a disproportionately low protein C level when compared with that of another vitamin K-dependent protein, such as factor II, VII or X.

Partial or complete protein S deficiency causes a tendency to venous thromboembolic disease very similar to that of heterozygous protein C deficiency. The use of warfarin or heparin is effective treatment. Neither protein C nor protein S deficiency has been clearly shown to increase the risk of arterial thromboembolism. A search for other defects in the protein C anticoagulant pathway, such as quantitative or qualitative deficiencies of thrombomodulin, is under way in many laboratories and may further increase our understanding of the pathophysiology of thromboembolic disease.

Antibody Testing for the AIDS Retrovirus—Implications for Clinicians

A NEW HUMAN RETROVIRUS (variously called LAV, HTLV-III or ARV) has been isolated from tissues of patients with acquired immunodeficiency syndrome (AIDS) and with lymphadenopathy in both Europe and the United States. Antibodies against this virus have been detected in a high percentage of AIDS patients, asymptomatic homosexual men and men with hemophilia. Investigations of blood donors implicated as the source of transfusion-acquired AIDS suggest that there may be a prolonged asymptomatic period of infectivity. Testing of all blood donors for antibody to the AIDS retrovirus (ARV) may soon be required. Enzyme-linked immunosorbent assays (ELISA) for ARV antibody will be used to screen blood units and those found to have the antibody will be discarded. This measure appears both practical and reasonable as a means of preventing future cases of transfusion-acquired AIDS.

The availability of this test will create several problems for practicing clinicians. First, positive tests will be found in persons not in any group known to be at risk for AIDS. Many of these ELISA results will be false-positive. Because confirmatory tests such as Western blotting or immunofluorescence are expensive, technically demanding, not widely available and of uncertain sensitivity, it will be difficult initially to determine which positive results reflect possible infectivity for others or an increased risk of AIDS developing. Despite this uncertainty, persons with repeatedly positive tests should be notified because they can take actions to reduce potential spread of the virus via sexual contact, child bearing or nonsexual transfer of body fluids.

The notification of a positive test result will have enormous emotional impact on most persons and requires that physicians be well informed about the limitations of the tests and implications of the results. Even if systems are developed to inform persons of their results through public agencies, many will seek reassurance and follow-up from their personal physicians.

The second problem for clinicians will be the skillful use of these tests for diagnosis. Because of the wide spectrum of clinical manifestations of AIDS-retrovirus infections and the high prevalence of the AIDS-retrovirus antibody in groups at high risk for AIDS, the diagnostic usefulness of finding the antibody in high-risk patients with unusual clinical syndromes will be limited. For example, should a gay man with idiopathic Bell's palsy or thrombocytopenia and a test positive for AIDS-retrovirus antibody be diagnosed as having an ARV-associated condition? While these tests will help to expand knowledge of the clinical spectrum of AIDS-retrovirus infections, they may also be confusing and misleading.

One possible solution to these problems is the development of tests to detect the AIDS virus directly in blood and tissues. This may be accomplished by growing retroviruses in cultures or detecting virus-specific antigens or nucleic acids. These techniques eventually may replace the soon-to-be released antibody assays. In the meantime, physicians will be faced with the difficult task of explaining and interpreting a test of uncertain significance to anxious patients.

New Antiarrhythmic Agents—Amiodarone, Mexiletine, Tocainide

UNTIL RECENTLY, antiarrhythmic drug therapy has been restricted to a few agents. Over the past decade, however, there has been a dramatic increase in the number of agents that have been or are soon to be released for clinical use. One drug, tocainide, has just been released for clinical use and two others—amiodarone and mexiletine—are subject to intensive clinical investigation.

Amiodarone

Amiodarone, an agent that prolongs myocardial refractoriness in almost all types of cardiac cells, is quite effective in the clinical management of supraventricular and ventricular arrhythmias and arrhythmias associated with the Wolff-Parkinson-White syndrome. In numerous clinical trials amiodarone effectively suppressed these arrhythmias in patients who did not respond to conventional antiarrhythmic drug therapy. There appears to be general agreement that it requires days, sometimes weeks or even, rarely, months for the full antiarrhythmic efficacy of oral administration of amiodarone to become manifest. There still exists some controversy regarding amiodarone's antiarrhythmic efficacy when given intravenously. The drug is most commonly given orally, usually with a loading dose of 800 to 1,800 mg a day during the first week, followed by a daily maintenance dose of 200 to 800 mg a day. Amiodarone seems to be well tolerated by most patients, but with the increasing use of this drug, several unwanted side effects have been recognized. A small percentage ($\leq 10\%$) of patients have to stop taking amiodarone because of more serious and even life-threatening side effects. These include refractory heart failure; pulmonary fibrosis; central nervous system side effects such as tremor, ataxia, paresthesia, headache and nightmare; sinus arrest, and exacerbation of ventricular tachycardia. Less alarming side effects include corneal microdeposits, with possible association of photophobia, thyroid dysfunction (hypothyroidism or hyperthyroidism), a peculiar bluish or slate-gray discoloration of the skin including the face and abnormalities on liver function tests. These complications may take several weeks or even months to disappear after the drug regimen is discontinued. Many investigators, therefore, have suggested that this drug

be used only in patients with serious arrhythmias unresponsive to routine therapy.

Mexiletine

Mexiletine is a structural analog of lidocaine that, however, is effective given orally. The oral dose ranges from 100 to 400 mg every six to eight hours. For urgent therapy, the intravenous route may be considered, with 200 to 250 mg given over five minutes, followed by an infusion of 60 to 90 mg an hour. Mexiletine is effective in suppressing ventricular arrhythmias; its definite role in the control of these arrhythmias, however, is still not defined. Most of the side effects occur during the initial period of therapy and later disappear in most patients during maintenance therapy. These side effects are frequently of central nervous system origin, including tremor, nystagmus, diplopia, dizziness, dysarthria, paresthesia, ataxia and confusion. Gastrointestinal side effects are common and include nausea, vomiting and dyspepsia. Thrombocytopenia and the presence of antinuclear antibody rarely occur but have been reported in some cases. Side effects are more likely to occur at plasma concentrations of greater than 1.5 to 2 μg per ml, which is very close to the therapeutic level. Cardiovascular effects of mexiletine are infrequent and include hypotension, bradycardia and exacerbation of arrhythmias. Mexiletine is generally well tolerated, however.

Tocainide

Tocainide is another structural analog of lidocaine and is, like mexiletine, effective against ventricular arrhythmias when given orally. Both tocainide and mexiletine have relatively long half-lives (12 hours).

In a number of clinical studies, tocainide has decreased the frequency of ventricular premature depolarizations, with variable side effects on ventricular tachycardia. The precise role of tocainide and the clinical setting in which the drug may eventually be used is still not defined. It would appear that tocainide will exert its antiarrhythmic efficacy at plasma concentrations above 6 μg per ml. The oral dosage regimen for tocainide is usually 400 to 600 mg every eight hours. Tocainide is generally well tolerated. Side effects include central nervous system disorders such as tremor, headache, sweating, altered hearing, dizziness, nervousness, hot flashes, paresthesia, blurred vision or diplopia, anxiety and lightheadedness. Gastrointestinal complaints, however, are more common and include anorexia, vomiting, nausea, abdominal pain and constipation.

These three antiarrhythmic agents hold the potential for dramatically increasing a clinician's ability to control serious cardiac arrhythmias. However, with their use comes the additional problem of serious side effects that must be carefully monitored by the physician.

Clinical Use of Portable Insulin Pumps

AN ARRAY OF evidence supports the view that diabetic complications are attributable to the metabolic derangements caused by elevated blood glucose levels. This concept has been translated to patient care—thus the increased emphasis on blood glucose control. Ideally, changes in blood glucose levels would automatically be sensed and insulin appropriately released into the portal circulation. This could be accomplished with pancreatic islet cell transplantation or by an implantable glucose-controlled ("closed loop") insulin infusion system, a so-called artificial pancreas. While research into these areas continues, the development of blood glucose self-monitoring and patient-controlled external medication infusion pumps permitted clinical trials and now general clinical use of "open-loop" continuous subcutaneous insulin infusion (CSII) systems.

These insulin infusion devices, which use only short-acting insulin, consist of a syringe or an insulin reservoir in conjunction with a battery-operated pump controlled by an electronic mechanism that is designed for a relatively continuous infusion rate of insulin, the basal rate. This basal rate is supplemented by an increase in the insulin infusion rate controlled manually by the patient at mealtimes, the meal bolus. Patients must regularly—at least three to four times a day—monitor capillary blood glucose responses to the insulin infusion to insure adequate insulin doses. The insulin is delivered through disposable plastic tubing and a subcutaneous needle or catheter that is taped in place for one or two days. The newer pumps have alarms for battery failure, overdelivery and high pressure in the outflow system. The larger and nonprogrammable early pumps have been largely replaced by smaller, often preprogrammable devices that are easily concealed and do not interfere with most daily activities. Multiple basal infusion rates can be used for changing activity levels, and meal bolus injections can be adjusted for variable size, quality and timing of meals. These features provide patients with more freedom in their daily lives.

A policy statement from the American Diabetes Association states the primary indication for CSII:

> Failure to achieve an acceptable level of diabetic control in certain type I diabetic subjects with unusual fluctuations in blood glucose levels, despite intensive efforts with proper diet and multiple injections of insulin in single or mixture form and high patient motivation and compliance.

These guidelines include patients who have hyperglycemia associated with elevated glycosylated hemoglobin or patients with frequent hypoglycemic episodes as a result of trying to maintain blood glucose control. Hyperglycemia during pregnancy has been shown to be a definite risk to the fetus, and CSII in this setting can be especially useful for preventing diabetic complications of pregnancy. Some patients with insulin allergies are sensitive to the protamine or

zinc in the insulin preparations. These problems can be eliminated or minimized by infusing short-acting crystalline zinc insulin or, if necessary, a zincfree sodium insulin. Diabetic patients without any of the above indications also have used CSII to obtain more freedom in their life-styles—less restriction in meal timing and easier changing of work shifts or travel. Most patients have an improved sense of well-being when using CSII and they prefer to continue to use it even if blood glucose control has not improved. Possibly this is the result of a psychological effect of being in charge of their disease (the internal locus of control).

Data from our University of California, Irvine, clinic shows no statistically significant improvement in hemoglobin A_{1c} levels during 98 patient-years of CSII use in 46 patients. The mean hemoglobin A_{1c} value for these patients, however, was only mildly elevated (8.4%) before pump therapy and was 8.1% during CSII use.

Three major complications of pump therapy are diabetic ketoacidosis, hypoglycemia and infections at the infusion site—all of which have been associated with mortality. Due to the use of short-acting insulin, ketoacidosis develops rapidly when the insulin infusion is interrupted by tubing occlusion, leakage or mechanical failure of the pump. The accumulation of insulin crystals appears to be the main cause of needle occlusions. Ketoacidosis may be severe before blood glucose levels rise significantly, and patients using CSII may present with "euglycemic" ketoacidosis—that is, severe ketonemia preceding the rise in blood glucose concentrations. Various studies have reported a 2 to 17.5 times increase in the rate of ketoacidosis associated with CSII use. In our clinic the ketoacidosis rate is high before CSII use (0.17 events per year) and remained unchanged after CSII use (0.2 events per year). Although less frequent in these patients, hypoglycemia has occurred due to pump "runaway" and inappropriate insulin dosage through patient or provider error. In our clinic, however, the frequency of serious hypoglycemic episodes (requiring a hospital visit), was reduced from 3.0 events per year before to 0.2 events per year during CSII use and 87% of patients reported a greater than 50% reduction or complete elimination of severe hypoglycemic episodes during CSII use. For patients with ineffective glucose counterregulation, we recommend CSII use but alter our lowest acceptable blood glucose concentrations upward to the 100 to 150 mg per dl range. This treatment has produced remarkable results as described above. Insulin preparations contain antibacterial agents, but the indwelling needle or subcutaneous catheter can be a conduit for local infections when left in one site too long.

Among the solutions to these problems are the use of buffered insulins, appropriate insulin dilutions and daily changing of the infusion set and subcutaneous site with antiseptic care during insertion to avoid occlusions and infections. Patients need detailed instructions and repeated rehearsals to ensure problem-solving ability. Providers who prescribe CSII use should be aware of the possible complications, and an experienced clinician should be available to patients at all times.

The expense of insulin pumps ($1,000 to $2,500 initial costs plus daily supplies) and the requirement for a high degree of patient knowledge, motivation and participation have limited CSII use. Despite these difficulties, an estimated 8,000 to 10,000 insulin pumps are in use in the United States today. It remains to be proved whether the original goal of preventing long-term diabetic complications in large patient populations through sustained normoglycemia can be realized with CSII any more effectively than with multiple subcutaneous insulin injections combined with self-monitoring of blood glucose levels. We view pump use as an alternative insulin administration method that is associated with some serious complications that must be thoroughly considered before being prescribed and used.

Human T-Cell Leukemia Virus (HTLV)

A VIRAL CAUSE of malignant conditions in humans has long been suspected, although there has been a paucity of confirmatory evidence. Recently, however, an etiologic association has been made between a unique type C retrovirus called human T-cell leukemia virus (HTLV-I), or adult T-cell leukemia virus (ATLV), and an unusual tumor of mature T cells in humans called adult T-cell leukemia/lymphoma. Originally thought to occur only in geographic areas where the virus is endemic, such as southwestern Japan and the Caribbean, the leukemic process has now been identified in other parts of the world, including the southeastern United States, parts of Africa and South America. This suggests that the virus is more widespread than initially thought. The onset of adult T-cell leukemia/lymphoma may be indolent; recently it has been recognized that clinically well patients may have antibodies to HTLV-I for many years before the development of symptomatic disease. The usual presentation of adult T-cell leukemia/lymphoma is abrupt, however, and is characterized clinically by lymphadenopathy, hepatosplenomegaly, skin lesions that may be clinically and pathologically indistinguishable from those of mycosis fungoides, hypercalcemia, lytic bone lesions and interstitial pulmonary infiltrates due either to lymphomatous infiltrates or to opportunistic infections. Involvement of the central nervous system is not uncommon. Malignant cells are found in the peripheral blood of most patients at some time during their course. Treatment usually consists of combination chemotherapy, though responses are generally short-lived, with few patients surviving more than a year.

The malignant virus-infected cells found in the peripheral blood and tissues of patients with adult T-cell leuke-

mia/lymphoma show a great deal of cytologic variation; typically they are medium-sized pleomorphic lymphocytes with lobulated nuclei. The vast majority possess mature T-cell surface markers characteristic of the helper phenotype (OK T4), although, interestingly, they function as suppressor cells.

HTLV infection is exogenously acquired. The mechanism of its transmission is not yet known, but it appears that sexual contact and prolonged exposure are important. Epidemiologic studies show an increased incidence of antibodies against HTLV-I in clinically normal spouses of patients with adult T-cell leukemia/lymphoma. Transmission of the virus has been accomplished in vitro by cocultivating HTLV-positive T-cell lines with normal cord blood or bone marrow T cells; the newly infected cells acquire the nuclear antigens (p19 and p24), specific reverse transcriptase activity and morphologic characteristics of the HTLV-positive T-cell lines. Once this RNA virus has infected the host cell, it replicates using its specific reverse transcriptase and integrates its genetic material into host cellular DNA. The virus is T-cell tropic; its proviral sequence is found within DNA of neoplastic T cells but not within nonneoplastic B cells or somatic cells from the same host. The exact mechanism whereby HTLV causes neoplastic transformation is not known, but it does not appear to carry an *onc* gene.

The human T-cell leukemia/lymphoma virus that is associated with adult T-cell leukemia/lymphoma (HTLV-I) belongs to a family of related T-cell-tropic viruses. HTLV-II has been isolated from the serum of a patient with hairy cell leukemia. HTLV-III has been identified in blood and saliva of patients with the acquired immunodeficiency syndrome (AIDS) and in patients with the AIDS-related complex, including the lymphadenopathy syndrome. Although Koch's postulates have not been fulfilled, it is currently believed that HTLV-III is the cause of these AIDS-related disorders. The discovery of this unique family of retroviruses has provided an important link in our understanding of the pathogenesis of a variety of T-cell disorders.

Female Adolescents With *Chlamydia*

Tomorrow's Candidates for In Vitro Fertilization?

IN THE PAST decade *Chlamydia trachomatis* has been recognized as our most common sexually transmitted pathogen.[1] It is estimated that 3 million chlamydial infections occur each year in the United States.[2,3] Surveys of symptomatic and asymptomatic female populations have identified age and ethnicity as important risk factors for chlamydial infection. For example, a study of seven different family planning clinics in the San Francisco Bay Area found that 16% of adolescent girls seeking birth control advice had chlamydial infection.[4]

The report by Eagar and co-workers in this issue further helps to define the problem. In this study, *C trachomatis* was the most common sexually transmitted disease agent recovered from the screened adolescent girls in all clinic settings, occurring overall at about three times the rate for gonococcal infection. Higher chlamydial infection rates were found for blacks. It is clear that chlamydial infections cross ethnic and socioeconomic boundaries. A higher ratio of chlamydial to gonococcal infection was found in the more economically advantaged white population—as in previous reports.

Chlamydial infection has been reported in as many as 37% of pregnant adolescents.[5] Attack rates for infants with perinatal exposure to *C trachomatis* are about 60% to 70% for any infection, 35% for conjunctivitis and 15% to 20% for the most serious complication, chlamydial pneumonia in infants.[6] Chlamydial infection in infants is preventable. Routine screening of high-risk pregnant women, followed by treatment with erythromycin of those found infected, has been shown to be a cost-effective preventive strategy.[7]

The most important complication of sexually transmitted chlamydial infection is acute salpingitis. Pioneering studies in Sweden, recently confirmed in the United States, have found that approximately one in four patients admitted to hospital with acute salpingitis had upper genital tract infection with *Chlamydia*.[8-10] It is estimated that salpingitis is ten times more likely to develop in a sexually active 15-year-old girl than in her 25-year-old counterpart (1:8 versus 1:80).[9] If one assumes that the infertility rate following a single bout of salpingitis is about 10%, then almost 1% of sexually active teenage girls will become infertile as a result of acute salpingitis each year. Acute salpingitis is a major public health problem, with direct medical costs well in excess of $1 billion each year.[11] Rising rates of ectopic pregnancies and involuntary infertility add to the dreadful toll this disease exacts. The evidence for its role in tubal factor infertility is convincing.[12]

It is imperative that we, as a nation, begin some formal efforts to control this epidemic. The measures suggested by Eagar and colleagues are appropriate: (1) Presumptive therapy is appropriate for conditions where *Chlamydia trachomatis* is known to occur at relatively high rates (endocervicitis, salpingitis, nongonococcal urethritis in men, gonorrhea and other sexually transmitted diseases.[13,14] (2) Routine treatment of sexual contacts is called for. (3) In those settings where high rates of chlamydial infections occur, antibiotics effective against *C trachomatis* should be used whenever possible. (4) High-risk populations should be screened. (5) Greater education concerning the risks and symptoms of chlamydial infection should be provided.

In addition, more effort is needed to educate health care providers as to the importance of chlamydial infections and the guidelines for managing them. The educational efforts must be specifically designed to be appropriate for adolescents and their health care providers. Diagnostic tests must be made more widely available.

Initiation of these steps may help to control chlamydial infection, yet there is an important missing link. Many data have been accumulated on the importance and prevalence of chlamydial infection in women because they routinely have pelvic examinations. Similar data are not available for men unless they are symptomatic or named contacts. If 15% to 20% of sexually active girls have chlamydial infection, what percentage of sexually active adolescent boys must also be carrying this organism? Without noninvasive screening methods for detecting asymptomatic infections in men, we can never hope to generate this type of information. Recent studies have stressed the prevalence of asymptomatic urethral infection in men.[15] Unfortunately, without reducing the youthful male reservoir, we shall never really control chlamydial (or gonococcal) infections. Preliminary studies suggest that evaluation of pyuria in first-catch urine specimens may have a high predictive value for urethral infection in adolescent boys.[16] If a urine specimen could be used for screening and diagnostic tests, a noninvasive tool for identifying the asymptomatic male reservoir may evolve.

Medicine in the Fabric of Society

IT IS NOW increasingly evident that medicine has become an integral part of modern society, particularly in America. The health care enterprise, taken as a whole, is one of the largest industries in the nation, and within it medicine plays a seminal role. But, in addition, in one way or another medicine has come to influence or be influenced by almost every facet of today's society. In this sense medicine is becoming an increasingly important part of what might be called the fabric of society. Why is this happening, and what is its meaning for physicians and the medical profession as a whole?

There may be at least three reasons why medicine is beginning to be so interwoven with a changing society. First, many of the great advances in medical science and technology not only affect the way physicians practice but have also begun to create significant ethical, social, economic and political problems with which society as a whole must now deal in one way or another. Second, modern society, with its growing social, economic, political and, above all, technologic complexity and interdependence, is itself creating all kinds of new problems for medicine and health care that require new responses by physicians and the medical profession. And third, modern society is after all a human society, made up of humans whose behavior and responses are genetically as well as experientially determined, and who for better or worse are individually unique and must react within the framework of their biologic nature to all the stresses of the increasingly complex world in which we all live. Medicine is the professional discipline that deals with human adjustment or maladjustment to the stresses in the internal and external environments of the individual persons who in the aggregate make up modern society. If the stresses are manageable and adjustment is adequate, then health and well-being prevail, but when this is not the case symptoms of stress or frank ill health appear in individual persons or in groups of people. Physicians and the medical profession, therefore, find themselves promoting health and wellness wherever possible, and where there is unhealth they proceed with the diagnosis, treatment and correction of whatever maladjustment is impairing health whether in the internal or external environment, or both. So, modern society being what it is, medicine is coming to pervade much of its fabric.

What then should medicine be in today's society? Or, put another way, what *is* medicine in today's society?

- Medicine is *personal*—and *biological*. Adjustment and maladjustment in health and illness are very individual and very personal, and the mechanisms of adjustment and maladjustment are fundamentally biological in the broadest sense of human nature and human behavior.
- Medicine is *professional*. Physicians have been set somewhat apart by society, and given special training and special privileges to serve their patients and the public. As professionals, physicians have set their own professional standards for their training and practice. This may be considered by some as elitist, but clearly it can be no other way.
- Medicine is *science and technology*. Its science and technology probe deeply into the nature and causes of illness, injury and emotional disorders, and the findings are applied to the promotion of health and well being, to prevention of ill health, to diagnosis and treatment to repair damage to the mind and body when ill health occurs and to restoring adequate adjustment to stress whether from a person's internal or external environment.
- Medicine is *art*. There is more to medicine than science and technology. The science is not exact and may never be. Furthermore, every person, whether sick or well, is unique, genetically and experientially different from everyone else. Medicine therefore has to be a human, caring relationship between doctor and patient (or the profession and the public, for that matter), with the art being to orchestrate the personal, cultural, scientific, technologic, social and economic factors that must be harmonized if there is to be health or if an unhealthy state is to be corrected in an individual or in the environment (society).
- Medicine is *social*. It is part of every known culture. The modern health-care enterprise is a complex social system, so far only poorly studied or understood. Social issues, growing out of the technical capabilities of modern medicine, are calling into question many of society's ways of doing things. In many ways medicine is actually a social science with much of this science yet to be developed.
- Medicine is *economics*. Medicine has become a significant part of the economics of modern society, and the economics of modern society has become a significant part of medical practice. Health care is a good product but it is costly. Medical economics is presently at center stage in health care and of much concern to both medicine and society.
- Medicine is *politics*. Medicine has been political in this country for more than a century. Its power has been, and still is, rooted in what is recognized as its competence in matters of health and health care. Now there is formidable competition in the political arena of health care. Medicine and health care have become everybody's business. The politics of medicine will not go away, and medicine badly needs a more identifiable constituency and a more positive program if it is to become truly effective politically.

There can be little doubt that the thread of medicine weaves through the fabric of today's society. It is not yet clear how strong this thread will be or just who will weave its pattern in the fabric. Will the pattern be decided by society? Probably so. But who will create the design? There is an enormous opportunity to weave (1) the underlying biology of human nature and human behavior, (2) the science, technology and art of medicine and (3) the social, economic and political realities of health and health care into a creative pattern in the fabric now being woven for the complex and interdependent society that is emerging in America today. An unanswered question is, does American medicine have the interest, the wherewithal or the resolve to be and be recognized as "physician to society," and in this role bring its skills to bear to help diagnose and treat the all-too-evident maladjustments in health and health care in this nation?

Case Reports

Computed Tomographic Findings in Orbital *Mucor*

MARK R. GREENBERG, MD
SCOTT M. LIPPMAN, MD
VERITY S. GRINNELL, MD
MARC F. COLMAN, MD
JOHN E. EDWARDS, Jr, MD
Torrance, California

MUCORMYCOSIS is an increasingly important infection in immunocompromised patients; knowledge regarding the variability of its clinical manifestations is expanding steadily.[1] The infection is of paranasal sinus origin and may involve the orbit secondarily via freely communicating foramina and venous channels.[2] Death often ensues when the infection spreads either into the cavernous sinus or the central nervous system.

Early diagnosis of rhinocerebral mucormycosis is crucial for a successful outcome.[3] Computed tomographic (CT) scanning is used to visualize many intraorbital pathologic abnormalities. The patient discussed in this paper had extensive orbital *Mucor* that appeared minimal on a CT scan. This inability of the scan to reflect the severity of infection prompted our review of the literature describing the use of CT scans for detecting this potentially fatal, opportunistic infection. The search showed that a disparity between scan findings and the severity of the disease is the rule rather than the exception. Recognition of this disparity has significant implications for appropriate diagnosis and management of orbital *Mucor*.

Report of a Case

A 62-year-old woman with agnogenic myeloid metaplasia had been treated with prednisone (20 mg per day) for two years, until she was referred for management of persistent bilateral pulmonary infiltrates. She presented to a community hospital with fever, rigors, shortness of breath and cough. A chest roentgenogram showed a left upper lobe infiltrate. Cultures of blood, sputum and a bronchoscopic biopsy specimen, however, were negative. The patient deteriorated clinically. Culture of an open lung biopsy specimen failed to show a causative agent and empiric therapy with broad-spectrum antibiotics was begun. Subsequently, a severe cutaneous eruption developed, presumably a reaction to the drugs, and her steroid dose was increased fivefold. At this time, she was transferred to Harbor/University of California, Los Angeles (UCLA), Medical Center.

On admission, antibiotic therapy was discontinued and the steroid dose was tapered. The patient's condition improved until the seventh hospital day when right-sided chemosis, proptosis and ophthalmoplegia developed over four to six hours. Within 24 hours there was complete loss of vision, of pupillary reflexes and of facial sensation on the right. Minimal ethmoid mucosal thickening was seen on plain sinus radiographs. A CT scan of the orbits done on the same day (Figure 1) showed thickening of the ethmoid sinus mucosa: the sphenoid sinus was clear. No bone destruction was evident, though there were proptosis of the globe and swelling of the medial rectus. Contrast enhancement was seen around the cavernous sinus but cavernous sinus thrombosis was ruled out by venography. The orbital apex was of normal density and no mass lesions were present. Broad-spectrum antimicrobial and amphotericin B therapy was initiated.

Because the patient's condition continued to deteriorate, the orbit and ethmoid sinuses were explored surgically. Although the tissues looked normal, biopsy specimens taken from the ethmoid mucosa and medial rectus muscle showed characteristic hyphae of *Mucor*. An orbital exenteration and partial maxillectomy were done; extensive retroorbital avascular necrosis and destruction of the orbit by the invading organisms were found. Despite a dosage of 3 grams of amphotericin B given over subsequent weeks, intracerebral extension of the infection developed, to which the patient succumbed.

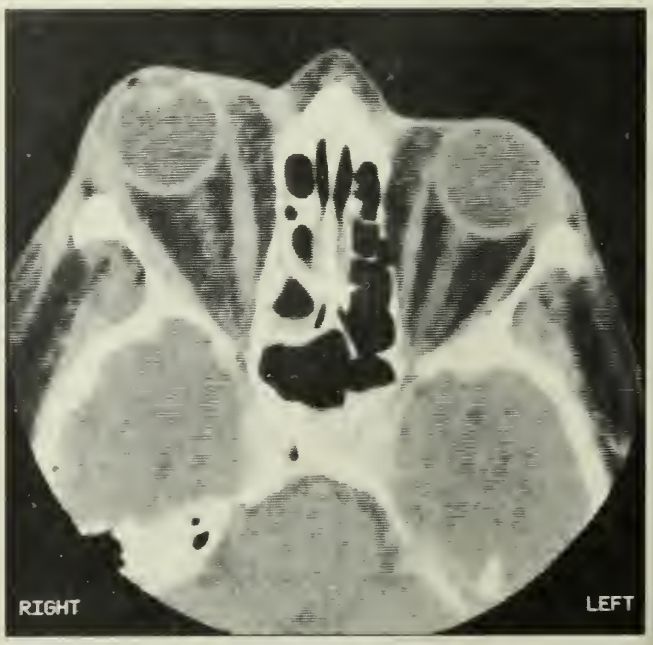

Figure 1.—A computed tomographic scan showing mild opacification of the ethmoids, proptosis of the globe and thickening of the medial rectus muscle on the right. Note absence of bone involvement or evidence of a retroorbital mass or displacement of retroorbital structures.

(Greenberg MR, Lippman SM, Grinnell VS, et al: Computed tomographic findings in orbital *Mucor*. West J Med 1985 Jul; 143:102-103)

From the Departments of Medicine and Radiology and the Division of Otolaryngology, Department of Surgery, Harbor/UCLA Medical Center, Torrance, California. This is Manuscript No. 61 of the California Collaborative Universities Mycology Research Unit.

Discussion

Computed tomography of the orbit was first described in 1974. Since then it has been used extensively to visualize intraorbital trauma, tumors and bacterial infection.[4-8] Descriptions of the findings in patients with intraorbital *Mucor*, however, are limited.[9-12] Most reports are restricted to single cases. In two of these single-patient case reports, the CT scan showed evidence of proptosis and medial rectus thickening,[9,10] and one patient was reported to have thickening and displacement of the medial rectus, increased density of the orbital fat and venous engorgement.[11] In all of these individual case reports, there was evidence of extensive sinus opacification on the CT scan.

The only series of cases has been compiled by Centano and co-workers, who reported the cranial CT scan findings of ten patients with rhinocerebral *Mucor*.[12] Extraorbital findings of proptosis (present in half the cases) and sinus mucosal abnormalities (present in seven patients) were common. Pleuridirectional tomography was more sensitive in detecting bony involvement of the sinuses (three patients) than CT scan (one patient). Extensive intraorbital abnormalities were not commonly seen by CT scan; four patients had no intraorbital abnormalities and three had only lateral displacement of the medial rectus. Only three of the patients had an increased density of the orbital apex consistent with an inflammatory mass.

In the scan of our patient (Figure 1), there was mild opacification of the ethmoids and thickening of the medial rectus muscle. Both the optic nerve and orbital apex were normal, however, and there was no bone involvement. The medial rectus thickening was similar to the previously described cases and apparently is a consistent finding. This muscular thickening may represent the earliest finding in orbital *Mucor*. It is a nonspecific sign, however, and the most common CT finding in cases of orbital pseudotumor.

We conclude from both our experience with this patient and from reviewing the English language literature that CT scan findings in orbital *Mucor* may be surprisingly minimal in the presence of advanced disease. Anticipated findings of a retroorbital mass with displacement of retroorbital structures and findings suggestive of massive tissue destruction are not necessarily typical CT findings and their absence should not delay an aggressive pursuit of the diagnosis of orbital *Mucor*.

Addendum

Two additional CT scan findings in cases of orbital *Mucor* have been reported: Kilpatrick and co-workers have described nonenhancement of the superior ophthalmic artery and vein,[13] and Anderson and colleagues have reported widening of the pterygomaxillary fissure.[14]

Tuberculous Peritonitis Developing in a Case of Documented Peritoneal Carcinomatosis

MAURIE MARKMAN, MD
San Diego

TUBERCULOUS PERITONITIS is an uncommon disease, particularly in the United States.[1] However, the rarity of this condition does not diminish the necessity of correctly making the diagnosis as therapy can be curative, whereas the disease left untreated is frequently fatal.[1-4] In this report, the case of a patient with histologically documented peritoneal spread of gastric carcinoma in whom tuberculous peritonitis developed is presented to emphasize the difficulty and importance of making this diagnosis in the presence of intra-abdominal malignancy.

Report of a Case

A 32-year-old Japanese woman presented to the UCSD (University of California, San Diego) Cancer Center for consideration of experimental intraperitoneal chemotherapy for gastric carcinoma. One year earlier she had had a subtotal gastrectomy for adenocarcinoma of the stomach. Four months before being seen at our institution, an umbilical mass was noted that on biopsy proved to be adenocarcinoma. Three months later an abdominal wall mass was detected. The patient had an exploratory laparotomy, which showed numerous peritoneal implants on the serosal surface of the small and large bowel and on the surface of the liver. A biopsy specimen (reviewed by several pathologists) confirmed the presence of recurrent tumor. A Tenckhoff catheter was placed and a regimen of experimental intraperitoneal chemotherapy of cisplatin, cytarabine and doxorubicin hydrochloride was begun.[5] Corticosteroids were included in the antiemetic regimen used. Ascites was noted on an ultrasound examination done to assist in catheter placement. At the time of initiating therapy, a left upper lobe pulmonary nodule not seen on previous chest x-ray

films was noted and, because the physicians caring for the patient initially suspected the nodule to represent metastatic gastric cancer, no further diagnostic evaluation was undertaken to rule out other causes of the lesion. Specifically, sputum specimens for culture were not obtained and a skin test for tuberculosis was not applied. The chest x-ray film also showed biapical scarring consistent with old granulomatous disease. The patient's maximal temperature in hospital was less than 38°C and she said she did not have respiratory tract symptoms. Peritoneal fluid cell counts, protein values and cytologic findings are shown in Table 1.

A month later the solitary pulmonary nodule had enlarged substantially. The patient remained afebrile but had lost weight and had increased ascites. A specimen of a transbronchial biopsy done to document the presence of metastatic disease showed only chronic inflammatory cells. Washings were negative for mycobacteria on acid-fast bacillus stain. Cultures of specimens obtained at the time of bronchoscopy eventually showed no growth of *Mycobacterium tuberculosis*. A purified protein derivative (PPD) skin test was done that was positive despite the fact that the patient was intermittently receiving steroids as antiemetic agents. A second course of intraperitoneal chemotherapy was administered.

Three months after presenting to our institution, the patient remained afebrile but her appetite was poor and her weight had fallen 10 kg (22 lb). An abdominal computed tomographic (CT) scan showed a pronounced increase in ascites compared with an earlier study, with probable peritoneal implants on the bowel and peritoneum. A percutaneous lung biopsy specimen again showed only inflammatory cells. However, specimens of both the biopsy material and the peritoneal fluid grew *M tuberculosis*. Unfortunately, before an antituberculous regimen was started, a small bowel obstruction developed. She underwent a bypass procedure to relieve the obstruction when conservative measures failed. At the operation the bowel was completely matted together by extensive adhesions. A biopsy specimen of material believed to represent tumor showed extensive necrotizing granulomatous inflammation without evidence of tumor. Postoperatively the patient was placed on a regimen of triple-drug antituberculous therapy. Following a slow postoperative recovery, she was able to eat normally and recovered her lost weight. She continues to receive antituberculous therapy and, except for intermittent abdominal pain most probably due to extensive adhesions, the patient remains clinically stable and without evidence of recurrent cancer 18 months following documentation of widespread peritoneal carcinomatosis.

Discussion

Tuberculosis developing in association with neoplastic disease is a well-recognized clinical problem. In a series of patients from a large cancer hospital, 9 of 1,646 patients with adenocarcinoma of the stomach seen between 1950 and 1981 were found to have tuberculosis at some time during the course of their disease—an incidence of 55/10,000 patients at risk.[6] In none of these patients was tuberculous peritonitis stated to have developed and the difficulty of diagnosing tuberculosis in this clinical setting was not commented upon.

*Months following presentation to the UCSD Medical Center, San Diego.

Our patient had several predisposing factors to the development of active tuberculosis. First, she was born in Japan and had only recently moved to the United States. The incidence of tuberculosis is presently ten times higher in Japan than in the United States.[7] Second, the patient had had a subtotal gastrectomy for gastric cancer. This procedure increases the risk for the subsequent development of tuberculosis, most probably due to malnutrition.[6,8] Third, the patient was treated with chemotherapeutic agents and steroids, which are immunosuppressive. Steroids, in particular, have been implicated in the high rate of tuberculosis associated with lymphoreticular malignancy.[6,9]

The signs and symptoms of tuberculous peritonitis and peritoneal carcinomatosis are almost identical.[10] Both are associated with exudative ascites, weight loss, pain and abdominal masses.[1-4,11-17] While fever is more likely to be associated with infection, in cases of tuberculous peritonitis fever may be absent[1,3,4,11,15-17] and it is common for cancer patients (particularly those with liver metastasis) to have low-grade fevers. The finding of predominantly mononuclear cells in the ascitic fluid (Table 1) should suggest the possibility of tuberculous infection even if cultures are negative.[1,2,11,17] One report suggests a significantly higher rate of culture positivity if at least 1 liter of ascites fluid is cultured rather than the small volume (less than 100 ml) normally obtained during a diagnostic paracentesis.[2]

While the finding of a positive PPD skin test in a patient such as the one in this report should raise a strong suspicion for the presence of *M tuberculosis*, a major portion of the population of Japan has been exposed to this agent, and a positive PPD cannot be equated with the presence of active disease.[7] Also, in an immunocompromised host, a negative PPD skin test does not exclude the presence of tuberculosis as the patient may be anergic. Therefore, several skin tests should be applied when evaluating immunocompromised patients (steroid therapy or cancer) for the presence of tuberculosis.

Recently, it has been suggested that the CT scan may be helpful in the differential diagnosis of tuberculous peritonitis,[18] but the radiographic findings are relatively nonspecific and in our patient suggested progressive intra-abdominal tumor. The finding of an enlarging pulmonary nodule in a patient with known intra-abdominal malignancy would suggest the presence of metastatic tumor. However, cavitation of the lesion or rapid growth (as in this case) should raise the suspicion of an infectious cause.

The importance of correctly diagnosing tuberculous infection, particularly in patients with concomitant malignant le-

sions, is more than of academic interest and cannot be overemphasized. The disease, even in its advanced form, is curable with appropriate antituberculous medications, but the success of therapy improves when it is instituted early.[16] In a patient in whom tuberculosis is even considered in the differential diagnosis, it is imperative that cultures be adequately done to rule out this diagnostic possibility. Any biopsy specimens obtained in such patients (transbronchial, peritoneal, bone marrow) should be sent to a microbiology laboratory with specific instructions to culture for *M tuberculosis*.

At the time of exploratory laparotomy, a large biopsy specimen failed to show histologic evidence of tumor. While this finding could certainly represent sampling error or a dramatic response to the intraperitoneal chemotherapy, gastric cancer is only modestly sensitive to the currently available agents and complete remissions are extremely rare.[19] In addition, even in patients responding to therapy, an 18-plus month survival from the time of diagnosis of an extensive intra-abdominal metastatic tumor with no current evidence of active disease is very unusual.

Two retrospective analyses of patients with lung cancer undergoing surgical resection showed improved survival for those patients in whom a postoperative empyema developed.[20,21] It was speculated that the nonspecific immune response induced by the infection resulted in tumor cell kill and an increased survival rate. In a rat transplantable tumor model, it has been found that the intrapleural injection of bacille Calmette Guérin (BCG) vaccine can suppress tumor growth.[22] Similarly, while the benefit of intrapleural administration of BCG following curative surgical treatment of lung cancer remains controversial,[23] one group has shown a small but statistically significant improvement in survival for patients with stage I non-small cell lung cancer receiving intrapleural BCG plus isoniazid compared with a control group receiving only isoniazid.[24,25] No benefit could be shown for patients with stage II or III lung cancer in this study. It is interesting to speculate that the intensive inflammatory response elicited by the *Mycobacterium* infection shown at the operation may have resulted in significant tumor cell kill and be responsible for the patient's remarkable clinical course.

In summary, this case emphasizes the similar clinical and laboratory features of peritoneal carcinomatosis and tuberculous peritonitis. A high index of suspicion for the latter disease was finally responsible for the correct diagnosis being made and appropriate therapy being instituted. In addition, this case underscores the importance of strongly considering in the differential diagnosis of a complex case treatable diseases, especially when the alternative explanations have limited therapeutic implications.

Granuloma Inguinale in a White Teenager—A Diagnosis Easily Forgotten, Poorly Pursued

WILLIAM A. GROWDON, MD
THOMAS B. LEBHERZ, MD
J. GEORGE MOORE, MD
GEORGE D. MASON, MD
GENE PARKS, MD
LINDA GOLDMAN, MN, RNP
Los Angeles

THE CONDITION variously known as granuloma inguinale, donovanosis or granuloma venereum is an uncommon disease process producing genital ulcerations that can be quite locally destructive and are known for their chronicity. The disease is most commonly seen in the southeastern United States. Although it is mandatory that this venereal disease be reported to the health department, many physicians are unaware of this fact, which may lead to underreporting. It is a relatively rare disease in California (Table 1). Granuloma inguinale can be easily diagnosed, although sometimes it is overlooked in differential diagnosis because of its rarity. The purpose of this report is to present a case of granuloma inguinale occurring in a white teenaged girl from California who suffered from a

chronic ulcerative vulvar lesion for several months before the condition was diagnosed as granuloma inguinale. We also review the clinical manifestations, diagnostic techniques and therapeutic regimens related to granuloma inguinale.

Report of a Case

The patient, an 18-year-old nulligravida woman, presented to the University of California, Los Angeles (UCLA), with a ten-month history of painful vulvar ulceration. She had been sexually active for two years. The first sexual partner had been a "casual contact" some weeks before she had begun a steady relationship with her current sexual partner of 11 months' duration. The first partner had traveled to New Orleans before their sexual contact.

The patient had an ulcer that started as a very sore, small spot in the left vulvar area beginning ten months before the examination. She noted dysuria, increased vaginal discharge and local itching and went to see the first of eight physicians. Specimens from the patient were cultured for gonorrhea, herpes and routine culture and sensitivity several times over the subsequent ten months. These tests, including five separate serologic tests for syphilis (VDRL), were negative. During this ten-month period the patient took courses of antibiotics, usually for only a week, including ampicillin, doxycycline hyclate (Vibra-Tabs), erythromycin and cephalexin (Keflex). A course of amoxicillin and cefaclor (Ceclor) was also taken. After some of these therapies there was a waning of the ulcerative lesion; the ulcer returned persistently, however. The patient's current sexual partner was examined by a physician and was told that he had no lesions or disease. Despite the vulvar ulceration, the patient would intermittently have coitus when the ulcer was "almost healed." After sexual activity the ulcer would at times exacerbate, and the patient's physician felt that this activity was causing local trauma leading to the problem. When the patient came to the UCLA Vulvovaginitis Clinic, she had not been taking antibiotics for three weeks. The ulceration was being treated by local measures such as sitz baths and was becoming increasingly painful.

On physical examination, including vital signs, the following abnormalities were found. A mildly tender left inguinal adenopathy was noted. There was a 2 by 2.5 cm, exquisitely tender, soft ulceration involving the left labium majus and perineal body (Figure 1). The ulceration had a well-defined border and appeared to have superficial infection and local induration with hypertrophic granulation tissue at the edges. There were no lesions on bimanual examination and inspection of the cervix, vagina and rectum.

Laboratory tests (UCLA Clinical Laboratories) disclosed the following values: A leukocyte count of 10,600 per μl, a differential of 65% segmented forms, 6% band cells, 4% eosinophils, 1% basophils, 18% lymphocytes and 6% monocytes; hematocrit was 43.1%. Urine culture and sensitivity were negative. Tissue specimen cultures were negative for *Hemophilus ducreyi*,[1] *Neisseria gonorrhoeae* and herpes virus[2]; culture of the ulcer bed was positive for penicillin-resistant *Staphylococcus aureus*; VDRL was negative. A wet mount of a specimen from the lesion for dark-field examination was negative for *Treponema pallidum*. A "touch preparation" of the ulcer was *positive by Giemsa stain for Donovan bodies* (Figure 2). A vulvar biopsy specimen showed chronic and acute ulceration without evidence of viral cytopathic effect.

Because of an allergy to tetracycline, the patient was treated with chloramphenicol, 50 mg per kg per day, divided in four doses every six hours. After seven days of this treatment, the ulcer responded by a 30% decrease in size, less induration and pain and evidence of healing by reepithelialization with no secondary infection. Antibiotic therapy was continued and the patient was monitored frequently. After 23 days of a regimen of oral antibiotics, the ulcer had completely reepithelialized, but there was moderate residual scarring (Figure 3).

Following this ordeal the patient requested and was referred for psychological therapy with regard to her future sexuality. It was noted that she was showing substantial depression and had negative feelings concerning future sexual relationships and sexual functioning after this chronic illness.

Discussion

The first case of granuloma inguinale was reported in the United States in 1913,[3] although the earliest description of the disease came from India in 1882.[4] In the early 1900s, Don-

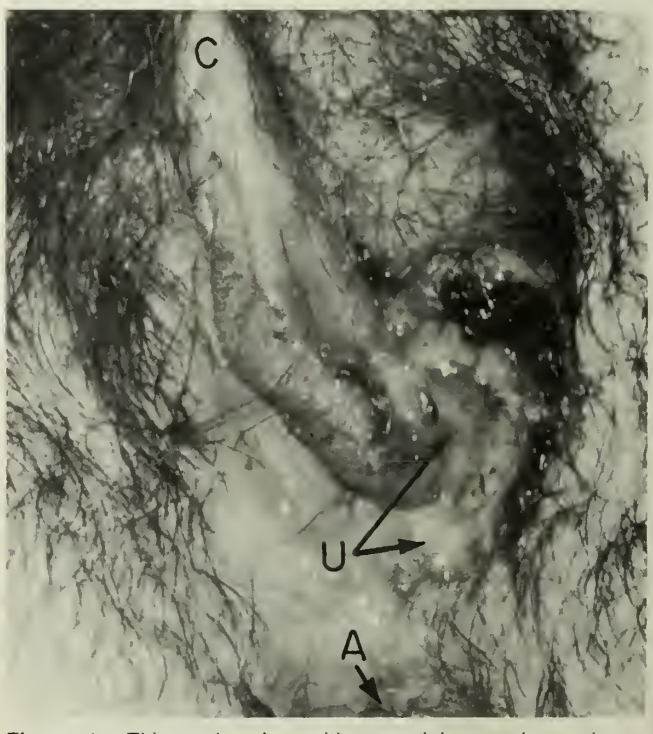

Figure 1.—This tender ulcer with a serpiginous edge and surrounding induration was photographed during the patient's first visit. **A** = anus, **C** = clitoris, **U** = ulcer of granuloma inguinale

ovan described the agents that he suspected caused this disease, referring to them as "epithelial cell parasites" due to intracellular protozoa,[5] thus the term donovanosis, which today is used preferentially as the identifying nomenclature in some articles. The term "granuloma inguinale" is attributed to Crocker in his treatise on tropical diseases of the skin.[6] The bacterial cause of this disease was not established until the early 1940s. Even today Koch's postulates have not been satisfied in determining the precise cause or mechanism of the disease process.[7]

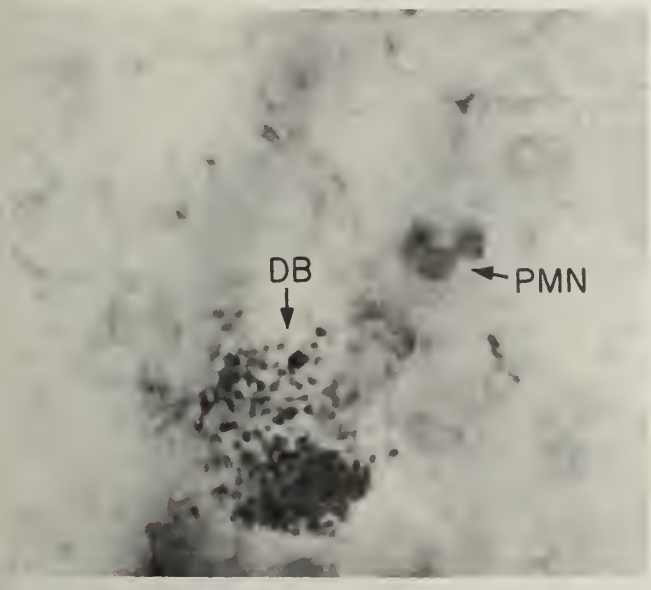

Figure 2.—Oil-immersion microscopy of the touch preparation of the ulceration, Wright's-Giemsa preparation, showed numerous histiocytes laden with Donovan bodies, an example shown here **(DB)** next to a polymorphonuclear leukocyte **(PMN)** (reduced from magnification ×2,500).

Figure 3.—Reepithelialization of the ulcer was evident four weeks after initiation of antibiotic therapy. **RU** = reepithelialized ulcer, **V** = vagina

Calymmatobacterium granulomatis, the Donovan bodies and presumed causative agents, was first cultured in the yolk sac of chick embryonated eggs,[8] defining a bacteriologic cause for granuloma inguinale. The yolk sac remains the most reliable culture mechanism. Although not available for clinical use because of the difficulty of cultivation, adaptation of yolk sac preparations to semisynthetic media has been successful,[9] with best growth in an anaerobic to microaerophilic environment. This bacterium has been studied ultrastructurally with electron microscopy[10] and is now classified as a nonmotile, encapsulated, pleomorphic, Gram-negative bacillus. Although sexual contact has been postulated as the most common method of acquiring the disease, it has occurred in people who are not sexually active. Transmission is unpredictable because there is a low incidence of infectivity in sexual partners of infected patients,[11] as cited in our case report. The disease is more common in the southeastern United States, in underdeveloped countries, in dark-skinned populations and in men.[12]

The incubation period varies from days to months.[13] The initial lesion, a papule, breaks down and becomes a beefy-red, granulomatous ulcer after a varying length of time. Unless secondary infection occurs, the ulcers are minimally painful; secondary infection increases pain greatly, however. The chronicity of the disease is its hallmark. In women, lesions are found most commonly in the labial or perineal areas. Vaginal and cervical lesions associated with abnormal genital bleeding have been reported.[14] A vesicovaginal fistula may also occur. In men, severe disease may erode and destroy the penis. In affected homosexual men, there is a high percentage of perianal involvement.[10] Secondary infection is common in lesions of women. Ulcerations are superficial with an irregular serpiginous edge and surrounding induration and have central hypertrophic granulation tissue. Dissemination of these lesions and death have been reported, but rarely.

Because tissue culturing techniques are not generally available, the diagnosis of granuloma inguinale is usually made using standard techniques that are more readily available throughout the United States.[15] The touch preparation technique involves either touching a glass slide to the granulation tissue of the lesion or preferably obtaining a small piece of tissue through biopsy and crushing the tissue between slides, then processing the slides either with Giemsa, Wright's or Leishman's stains. This permits identification of histiocytes laden with intracytoplasmic organisms (Donovan bodies). If the patient has been treated for a significant amount of time before, it may be necessary to repeat the process more than once to identify the agent. The organisms cease to exist in the lesion bed, at least by the above techniques, after a patient has had 5 to 14 days of tetracycline therapy.[10] Although serologic testing for this particular disease has been reported, it is not now clinically used.[12]

A longer-than-usual course of antibiotics is necessary to cure the disease compared with other typical venereal disease conditions. As seen in this case, despite several therapeutic regimens that included drugs stated to be effective against the disease, short courses of treatment may be ineffective. Tetracycline,[16] co-trimoxazole[17] and chloramphenicol[18] are effective against this disease. Streptomycin sulfate[19] has long been

considered an efficacious agent for the disease, but because of the problem of the route of administration, potential resistance and side effects, the oral agents are preferable. Penicillin is not effective and ampicillin[10,20] elicits variable and, at times, poor response. Because the drugs discussed above are contraindicated in pregnancy, erythromycin[21] is the current drug of choice, possibly with the addition of lincomycin.[22] No double-blind controlled studies testing the efficacy of treatment have been reported. Regardless of which agent is used, the usual week to ten-day course of antibiotics used in other types of bacterial infection does not seem long enough to eradicate granuloma inguinale, especially in its chronic form. Observation during treatment, extension of treatment until Donovan bodies are no longer identified on Giemsa touch preparations and a duration of treatment for at least three weeks give a high degree of success. Attempts at surgical excision should be avoided because the potential for spread of the infection exists and ultimate resolution with antibiotic treatment can be expected.

In the case of the patient we discuss, who was seen by eight physicians, only the last physician briefly entertained the diagnosis of granuloma inguinale and sent the patient immediately to a referral center for confirmation. There the diagnosis was made in short order with a touch preparation and the disease was treated effectively. Had treatment continued without diagnosis of this uncommon disorder, quite possibly the patient would have suffered extensive tissue destruction, requiring surgical reconstruction. The delay in diagnosis and successive unsuccessful courses of treatment over a prolonged period may be considered contributing factors leading to the request for psychotherapy regarding sexual dysfunction. Granuloma inguinale is a reportable disease of suspected venereal transmission; thus the case was reported to the public health department for follow-up.

Postoperative Small Bowel Intussusception

CARLOS O. ESQUIVEL, MD, PhD
PATTE J. BISHOP, MD
CLIFFORD MARR, MD
MARSHALL Z. SCHWARTZ, MD
Sacramento, California

ALTHOUGH RARE in adults, postoperative small bowel intussusception can account for as high as 16% of cases of intussusception in children.[1] Frequently the diagnosis of postoperative intussusception is delayed because the clinical manifestations are masked by a recent abdominal procedure and an inappropriately low index of suspicion for this diagnosis.

We recently treated three patients with postoperative intussusception, which cases illustrate the problems in making the diagnosis and the usual clinical presentation following intra-abdominal operations in children.

Reports of Cases

Case 1

The patient, a 9½-month-old female infant, was admitted to a regional hospital with a three-week history of intermittent fever, vomiting and diarrhea and constipation during the previous few days. On admission the temperature was 37.5°C (99.5°F). The abdomen was distended with hypoactive bowel sounds. Abdominal rebound tenderness or muscular guarding was not present. The remainder of the physical examination showed no abnormalities. The serum chloride level was 111 and carbon dioxide level 20 mEq per liter; the rest of the electrolyte values, a complete blood count and analysis of urine were normal. Roentgenograms of the chest were normal, but abdominal films showed dilated loops of small and large intestine. The admitting diagnosis was large bowel obstruction and an exploratory celiotomy was done. Both small and large bowel were dilated, but a mechanical obstruction could not be found. An incidental appendectomy was done. The postoperative period was complicated by persistent ileus and wound dehiscence presumably due to infection. Following surgical treatment of the wound dehiscence, the temperature remained elevated to 38°C to 39°C (100°F to 102°F). On the fourth postoperative day bowel function returned and the nasogastric tube was removed. A regimen of metoclopramide hydrochloride was begun for treatment of persistent abdominal distension. On the fifth postoperative day a bloody stool was passed and she was referred to our institution for further management.

(Esquivel CO, Bishop PJ, Marr C, et al: Postoperative small bowel intussusception. West J Med 1985 Jul; 143:108-110)

From the Division of Pediatric Surgery, Department of Surgery, University of California, Davis, Medical Center, Sacramento.

Submitted May 21, 1984.

Reprint requests to Carlos O. Esquivel, MD, PhD, Department of Surgery, UC Davis Medical Center, 4301 X Street, Room 257, Sacramento, CA 95817.

Upon admission she was dehydrated and the rectal temperature was 37.6°C (99.7°F). The abdomen was distended, tympanic and tender to palpation. The digital rectal examination showed pinkish mucus that was Hemoccult positive. The leukocyte count was 14,400 per μl with 47% segmented neutrophils, 8% band neutrophils, 33% lymphocytes and 12% monocytes. Except for a low serum chloride level, the rest of the laboratory values were within normal limits. The abdominal roentgenograms showed several dilated loops of small intestine with air-fluid levels consistent with intestinal obstruction (Figure 1). A barium examination of the colon showed an ileoileal intussusception (Figure 2) that was subsequently confirmed during a diagnostic celiotomy. The intussusception was located about 12 cm proximal to the ileocecal valve and about 15 cm of ileum was involved. There was obvious intestinal necrosis requiring resection and enteroenterostomy. The postoperative course was benign and she was discharged on the eighth postoperative day.

Case 2

The patient, a 7-month-old male infant with Hirschsprung's disease, was admitted for a Duhamel pull-through procedure. The diagnosis of rectosigmoid Hirschsprung's disease was made when he presented at 5 days of age with toxic megacolon treated by emergency colostomy.

On admission the infant weighed 9.5 kg. Results of physical examination were normal except for the presence of a sigmoid colostomy. A complete blood count, serum electrolyte values and results of a urinalysis were within normal limits. The operation was carried out without difficulty, but postoperatively there was a persistent ileus. On the fourth postoperative day bowel sounds were heard, though his abdomen remained distended. Roentgenography of the abdomen showed dilated loops of small bowel with air-fluid levels consistent with either a postoperative ileus or a mechanical obstruction. The serum electrolyte values remained within normal limits. A trial of nasogastric suctioning and intravenous fluid replacement for two days failed to resolve the obstruction and an abdominal exploration was carried out. An ileoileal intussusception was found. Although the involved intestine was edematous, there was no evidence of necrosis. Manual reduction of the intussusception was accomplished and the postoperative course was uncomplicated.

Case 3

A 9-month-old female infant with Hirschsprung's disease was admitted for a Duhamel pull-through procedure. The patient had a diverting transverse colostomy at the age of 2 months when Hirschsprung's disease was diagnosed. The physical examination on admission showed no abnormalities except for the presence of the colostomy. The complete blood count, serum electrolyte levels and results of a urinalysis were within normal limits.

Following adequate bowel preparation, closure of the colostomy and a Duhamel pull-through procedure were done without complications. On the third postoperative day flatus was passed and oral feedings were begun. On the fifth postoperative day emesis occurred and the abdomen became progressively distended and slightly tender to palpation. Bowel sounds were hypoactive and no masses were palpated. The serum electrolyte values remained normal. Roentgenography of the abdomen showed dilated loops of small bowel consistent with mechanical obstruction. A small bowel intussusception was suspected and she underwent abdominal exploration when this diagnosis was confirmed. It was possible to manually reduce the ileoileal intussusception. The remaining postoperative course was uncomplicated.

Figure 1.—An upright roentgenogram of the abdomen shows dilated loops of small intestine and air-fluid levels.

Figure 2.—Barium enema showing a dilated ileum proximal to a coil-spring mass consistent with an ileoileal intussusception. The diagnosis was confirmed at an operation.

Discussion

Postoperative small bowel intussusception is the second most common cause of intussusception in children and it accounts for from 5% to 10% of cases of postoperative small bowel obstruction.[1] It shows an equal distribution between boys and girls.[2] Frequently, it occurs following retroperitoneal or long abdominal operations, but it has also been reported following minor procedures such as appendectomy, lymph node biopsy or herniorrhaphy.[2,3]

Two thirds of the cases of postoperative intussusception reported in the literature became symptomatic within the first week and 90% became symptomatic within the first two weeks following a surgical procedure.[2] This was also observed in our cases. In the infant in case 3, symptoms developed following a transient episode of what appeared to be normal bowel function; this has also been previously noted.[2]

Awareness of this disorder is the most important factor in making the correct diagnosis. Unfortunately, the symptoms and signs are not obvious as they are frequently masked by the clinical manifestations of a recent abdominal surgical procedure. The classic symptoms and signs of spontaneous intussusception such as abdominal pain, the presence of a palpable mass and hematochezia are usually absent.[2]

A delay in the diagnosis can lead to serious complications and death.[2] Case 1 illustrates the complications of delayed treatment—segmental intestinal necrosis necessitating resection of the involved ileum. Although a barium examination of the colon was diagnostic in this patient, it is most often not helpful. Frequently the small bowel intussusception is sufficiently proximal to the ileocecal valve that adequate evaluation is not possible. In some patients with a competent ileocecal valve, no evaluation of the small bowel is possible. Finally, in patients who have had a recent colonic operation, a barium enema would be contraindicated.

The etiology of postoperative intussusception remains unknown. Several factors have been implicated, such as disordered motility and edema following a surgical procedure, local hypoxia, anesthetic agents, electrolyte disturbance and medications (particularly cancer chemotherapeutic agents).[1,2] In postoperative intussusception, a specific lead point has been reported in only about 8% of the cases.[2] A lead point was not identified in any of our patients.

Awareness of postoperative small bowel intussusception in children should lead to prompt diagnosis and avoidance of the potentially high morbidity and possible mortality. Although a barium enema study has infrequently been a useful diagnostic tool, prompt surgical exploration remains the best diagnostic and therapeutic approach.

Correspondence

The Editorial Board will be pleased to receive and consider for publication correspondence containing information of interest to physicians or commenting on issues of the day. Letters ordinarily should not exceed 600 words, and must be typewritten, double-spaced and submitted in duplicate (the original typescript and one copy). Authors will be given an opportunity to review any substantial editing or abridgement before publication.

Immunization for Measles

TO THE EDITOR: In "Measles Transmission in Medical Facilities"[1] in the March issue, Drs Dales and Kizer recommend "routine immunization of new medical facility staff members born since 1956 . . . who lack documentation of prior immunization or disease," because "serologic surveys in California have indicated that, currently, perhaps 10% to 15% of young adults (ages 18 to 22 years) are susceptible to measles." This would apply where there is a lack of an immunization record showing month and year of immunization or where the diagnosis of measles was not made by a physician. I question the need for that recommendation, because more than 90% of those who will be subjected to immunization are already immune.

In the prevaccine era, more than 90% of all Seattle area measles cases occurred among children under the age of 9 and the median age was 5.5. There were large measles epidemics in the 1966-67 and the 1968-69 measles epidemiologic years and lesser outbreaks occurred in later years. Live virus vaccine was extensively introduced through a school immunization program in the fall of 1967 and the program was carried out subsequently for several years. In the 1970s and 1980s, passage of state immunization requirements resulted in immunization of many susceptibles who had slipped through earlier plus the reimmunization of many children who could not adequately document previous immunization.

Would it not be more cost effective and equally efficacious to focus their recommendation upon areas where measles cases have been introduced and accept an adult's statement that he or she has had the disease and the vaccine? Most diagnoses of measles cases were not called to the attention of a physician during the years when measles was epidemic and persons over the age of 22 are unlikely to have any immunization records to prove that they were immunized. Moreover, at least half of the physician-diagnosed measles cases during the recent postvaccine era have proved to be wrong.

In the example cited, it should be noted that in 64% of the cases the patients were of school age or younger and most of them had not been previously immunized. Had they been, the outbreak might also have stopped before ten generations. There is a good chance that it would have stopped at one or two generations.[2,3]

Upright KUB Roentgenogram

TO THE EDITOR: I am one of the authors of the article "Spontaneous Colonic Drainage—A Rare Complication of an Amebic Liver Abscess" that appeared in the February issue.[1] I would like to correct a typographical error in one of the figures.

On page 254, Figure 2, right picture, the caption reads "Another upright chest roentgenogram taken immediately after the episode of diarrhea." The caption should read "An upright KUB roentgenogram taken immediately after the episode of diarrhea."

Please bring this correction to the attention of your readers.

Holmesian Skills in Medicine

TO THE EDITOR: My imagination was captured by Sherlock Holmes when I was a child. It was a joyful occasion when in medical school an esteemed professor led me in a Holmesian exercise in observation and deduction at the bedside. At that moment medicine became fun. Since that time, I have carried the same exercise to generations of medical students. We spend two minutes at the bedside in the intensive care unit, no touching or talking allowed. We then go out of sight of the patient and deduce the case history—which is always possible if the instructor uses his or her own powers of observation in choosing a patient. Most of my students react as I did.

"The faculty of deduction is certainly contagious." The reason for its contagion lies in the joy of seeing that which one might easily have overlooked and the power of deducing important conclusions from an instantly available fact. The charm of Sherlock Holmes is the joy he derived from making obvious that which to others was obscure. He made joy out of discipline where others made only drudgery.

There is accomplishment in mastering medical discipline, to give a complex medical presentation through to the last detail of a system review without omitting a significant detail. But there is joy in observing (as opposed to seeing, of course) the body language that says that a patient is getting well, or the small sign that makes a difficult decision easy. The disci-

pline to stand at a bedside keeping one's eyes busy and mind on the sensory input has become one of the lost arts. It's a pity, because the joy goes with it. On the other hand, there is no reason why those skills cannot be developed in a home study program. It is a skill that the best clinicians have, and I am pleased that Dr Miller has detailed the Holmesian connection.[1]

1. Miller L: Sherlock Holmes's methods of deductive reasoning applied to medical diagnostics (Commentary). West J Med 1985 Mar; 142:413-414

* * *

TO THE EDITOR: Contrary to popular belief,[1] the extraordinary gift of Sherlock Holmes was not his ability to deduce (to reason from general theories to particular facts), but to induce (to reason from facts to theories). Compared with his ability to induce, Holmes's ability to deduce was quite ordinary. For example, given the general premise that all unicorns have a single horn, Holmes—and the average 10-year-old child—could readily deduce that any particular unicorn has a single horn.

The ability for induction is characteristic of skilled medical diagnosticians, but medical diagnosis also entails deduction and observation. Consider the logical sequence of evaluating a patient:

A set of diagnostic possibilities—the differential diagnosis—is generated by induction from observed facts. From each potential diagnosis, additional findings are predicted by deduction. Then, the predictions are tested against observed data (for example, laboratory results or response to treatment) to support or rule out the diagnosis.

The distinction between deduction and induction is profound; it is equivalent to the difference between hindsight and foresight. Because he wrote with hindsight, Conan Doyle sprinkled clues he had deduced after the fact; clues contrived to perplex readers who—together with real detectives and physicians—must experience mysteries with foresight. Holmes, on the other hand, enjoyed the same perspective as Conan Doyle, without which his successful inductions were no more than lucky guesses; the data he induced from can be explained by any number of alternative hypotheses.

Because deduction can be probative but induction can prove nothing, physicians have long sought deductive methods of diagnosis; for example, collecting enough data to be conclusive and seeking pathognomonic signs. These wished-for methods are based on the premise that diagnostic categories can be completely defined as a collection of their known elements. However, disregarding identities (such as a tiny head equals microcephaly), completely defined categories and pathognomonic signs are merely imaginary products of inadequate knowledge.

In the ideal universe of scientific taxonomy, diagnostic categories comprise all facts pertaining to an illness—whether the facts are known or not. In the real world of clinical medicine, however, the known diagnostic categories cannot be more complete than the set of known facts—a set that is not only incomplete, but partially incorrect as well. In former days, for example, bizarre behavior, delusions and disordered thinking were diagnostic of witchery, but contemporary knowledge and diagnostic theories do not accommodate witchery. Similarly, contemporary diagnostic categories will be replaced, expanded, narrowed or deleted in the future because of enhanced knowledge and more sophisticated theories.

The belief in deductive methods of diagnosis encourages physicians to act as mere technicians—that is, as if findings dictate treatment with no need for diagnosis. Thus, if a person is delusional, chlorpromazine is indicated. If after treatment the person remains delusional, more chlorpromazine is indicated. The technician is blind to alternative diagnoses such as bipolar illness or drug toxicity.

Physicians cannot practice competent medicine by applying Holmes's fictional methods of diagnosis; they must recognize that both induction and deduction are needed for adequate medical assessment and treatment. Those physicians who abandon the logical foundations of their profession are charlatans, because their "science" is fictitious. Certainly, charlatans cannot reverse today's politically expedient trend of corrupting medical facilities into fix-it shops.

How Important Is Knowing It All?

TO THE EDITOR: As a primary care physician working in specialties (emergency medicine and family practice) that have considerable overlap with other specialties with regard to relevant medical knowledge, I do not feel the findings of Kronlund and Phillips[1] published in the April issue are very surprising. Neither are they necessarily much reflection on the competence of the physicians surveyed. They rather reflect the explosion in data relevant to the practice of medicine. I am sure this in large measure explains the increasing specialization and subspecialization of physicians. The practice of clinical medicine is usually not conceptually difficult, but human memory is simply not up to the task of "knowing it all" with the certainty required for the safe practice of medicine. Furthermore, the unique and creative aspects of human intellect (reason, assimilation, hypothesizing) are wasted in trying to do so. *Roundsmanship* too often passes for good judgment and replaces practicing the art of medicine compassionately.

I see widespread use of accessible and easy-to-use clinical computer data bases as a powerful means to free physician energy for thinking and assimilating, rather than memorizing. Such an approach will also be a major factor in alleviating one major source of residency stress—the perceived need to know it all—alluded to elsewhere in the same *WJM* April 1985 issue.[2,3] Paradoxically, I would probably end up having more facts at my finger tips using an easily accessible computer data base. At the moment I needed to know some fact and was, therefore, most interested and curious, I could ask the computer and instantly have the data sought. Consider this situation as opposed to being bogged down by the lengthy and sometimes fruitless searches of textbooks we all do, or simply cannot take the time to do, when we need to, during a busy clinic day. Too often the question is not answered, and the chance to learn and improve is lost. What is needed is a rapid,

easy-to-use data base. But it is unnecessary and unrealistic to expect it to be located in each physician's head, except pertaining to a relatively narrow specialty area.

A Treatment for Enuresis

To the Editor: I have been interested in the subject of enuresis for many years and have come up with the following observation and recommendation for treatment. I have observed the simple fact that the more one exercises and perspires the less one urinates. This is because in a sense the skin organ has function much like the kidneys, in that it also excretes liquid, not unlike urine.

Bearing these simple conclusions in mind, I have recommended that the enuretic person engage in continuous rhythm exercise, such as running, cycling, swimming or even walking briskly for one hour daily, preferably in the late afternoon, without replacement of fluids thereafter.

Barring the presence of infection or a congenital malfunction, I have been quite pleased with the results. In addition to this diuretic effort of the exercise program, the patients gain many fringe benefits of exercise which include a better feeling about themselves. This seems to help the patients as well.

I would be interested in other practitioners' comments on this simple treatment of enuresis.

Hitting Below the Belt

To the Editor: Since the House of Delegates of the American Medical Association passed a strong resolution for a ban on boxing, the pros and cons of such a move have made it not only to the front page but also to the editorial page.

The media, not often given to throwing bouquets to the AMA, were almost embarrassingly complimentary. Editorials spoke of the courage and the foresight of the doctors in taking this stand.

Medical associations from New York to California joined in the plea for a total ban on boxing. Even Howard Cosell now wants boxing banned!

It seemed that only those who would suffer a financial loss—the promoters, the boxing associations, the TV moguls—were willing to come out swinging against such a ban.

There were a few bleeding hearts who wept that by banning boxing we would be depriving young men from the minorities of a chance at the "big money."

Along with the public endorsement of a ban on boxing came the admission that it had little or no chance of being put into effect. A great idea but—because the average American man (and some women) seems to get a psychological lift out of sitting in front of the tube, beer in hand, watching one human wreak violence on another—a total ban will never come to pass.

There is one hope, one simple remedy, that has so far received little attention and has been mentioned only in passing by *JAMA*: total banning of blows to the head.

Simple as that.

We all know there is a ban on hitting a boxing opponent below the belt. One punch beneath the belt will bring a strong warning from the referee. A second or third may bring disqualification of the offending boxer.

Now, all men who have participated in contact sports have at one time or another experienced a blow to the gonads, and we well remember that the pain was excruciating. But it was temporary and our genitalia suffered no long-lasting injury, either to our sex drive or to our reproductive capacity.

Why then is hitting below the belt considered such a heinous act, when rendering repeated blows to the brain, an uppercut to the chin or a sharp left to the head is considered an expert exhibition of the fine art of boxing?

Hitting below the belt can give temporary pain, but repetitive blows to the head, from the Adam's apple up, can produce contusions, lacerations and hemorrhages from the brain stem to the gray matter. And it has been shown that this occurs even when protective headgear is used.

The quick-witted, physically superb Muhammad Ali, with his dancing feet, has been hailed as the greatest boxer of all time. More likely his legacy to tomorrow's generation will be a newly identified clinical entity—"pugilistic parkinsonism," a damaged brain syndrome characterized by a shuffling gait, glazed eyes and dull-witted mumbling speech.

A call for a total ban on boxing may, indeed, be a noble but futile gesture. But if hitting below the belt is so wrong, then certainly it is time for all physicians to cry out that repeatedly banging the brain of another human with the fist is gross, vicious violence.

Vietnamese Patients and Physicians

To the Editor: I have read, with interest, the article "Culture Shock—A Review of Vietnamese Culture and Its Concept of Health and Disease" by Dr Nguyen, published in the March issue.[1]

Being a Vietnamese physician myself, I would like to share some personal thoughts in regard to the treatment of Vietnamese patients. I sincerely feel that Vietnamese physicians would be most helpful to their compatriots by guiding them into the American values and way of life. I do not think "East is East, and West is West." Many of the basic human values are shared by ancient Oriental culture and American culture.

The Vietnamese should make an effort to erase their misplaced pride, and realize that there may be better ways than theirs. For example, it is erroneous to identify being late to appointments as a less stressful way of conducting business. Likewise, they should begin to ask what they could do to give back to America in return for all the goodness they have received from her. Respect is to be earned, not asked for. The Vietnamese will not earn respect by asking for special status because of being refugees.

"Topics in Primary Care Medicine" presents articles on common diagnostic or therapeutic problems encountered in primary care practice. Physicians interested in contributing to the series are encouraged to contact the series' editors.

BERNARD LO, MD
STEPHEN J. McPHEE, MD
Series' Editors

Most physicians who care for patients with chronic illnesses attempt to help them be as active, sociable and productive as possible. Yet the traditional history, physical examination and differential diagnosis are inadequate for assessing the full range of common health-related problems in chronically ill patients. Such patients, during periods when their medical condition is stable, are frequently most concerned about problems of physical, psychological or social functioning.

Quickly assessing how well a patient is functioning can be difficult in clinical practice. Patients with the same disease often function quite differently. One patient with rheumatoid arthritis might be restricted to the home and require considerable assistance eating, bathing and dressing, while another, with equally severe disease, might be an active member of the community and need only minimal help. The severity of the disease might be described by a patient's sedimentation rate, inflamed joint count or treadmill exercise results. Ability to function, however, should be described by a patient's capacity to carry out a broad range of usual daily activities, such as housekeeping and family or social life. In this paper we suggest how physicians might identify, manage and treat limitations of physical, psychological or social function.

Detecting Functional Limitations

No standardized method for detecting a patient's functional limitations currently exists. Usually, a concerned physician asks patients directly about their problems or about their usual daily activities. Some functional limitations may be obvious or quickly elicited, but the full extent of disability is often hidden. Comprehensively assessing function requires thorough inquiry, which takes time and may not always be feasible. A brief, systematically validated self- or family-administered questionnaire is therefore an ideal substitute for direct inquiry in many circumstances. A valid survey of functional status, like a laboratory test, can be used to compare one patient's abilities with others and the same patient's progress over time.

Several functional assessment questionnaires are available. Unfortunately, some are too long for general office use. Others are specifically designed for the elderly or are limited to a single aspect of function. We are currently testing a brief, comprehensive, functional assessment questionnaire* that is suitable for any English-speaking patient. Over the next decade, we expect that many such questionnaires will be developed to suit the needs of practitioners in a variety of settings.

Clarifying Problems of Physical, Psychological or Social Function

Suppose a review of a patient's performance on a functional status survey revealed the following limitations:

- Difficulty with using transportation,
- Trouble with taking care of the home,
- Very few social activities,
- No sexual relationships.

Suppose further that the patient (a woman) says that she has not had sexual relationships for 20 years but is not concerned about it, and that what really bothers her is difficulty

*This questionnaire is available from the authors upon request.

using a bus because, without transportation, she is unable to take part in social and community activities.

This patient's chief functional limitation is "difficulty with transportation," to which a physician's typical response might be to send her immediately to a social worker. A more effective response, however, would be to analyze the problem more carefully before deciding what to do about it. When the action of using the bus is divided into its component parts, the patient's problem can be defined more specifically and becomes amenable to solution.

Action . . .
Using the bus.
Basic Components . . .
Get dressed and ready to go.
Walk to the bus.
Climb onto the bus.
Pay bus fare.

The patient's major difficulty can be with any one of these components, and each suggests a different solution. In some cases, a change in medications may be the answer. (Is the patient so drowsy that she has difficulty getting ready to go?) In others, a social work consultation, an exercise program or behavior modification may be appropriate.

Setting Priorities Among Multiple Problems

As illustrated in the previous example, patients with chronic illness may have many functional limitations at the same time. Improvement is most likely when patients and physicians agree about the importance of a symptom or problem. Sometimes just showing a patient the list of problems identified on a questionnaire and asking which are most important will reveal a patient's priorities. Other questions that can give a physician a sense of which problems the patient may be motivated to solve include:

- What is the one thing you would most like to be able to do, but cannot now do because of your health?
- Under what circumstances in your daily life does your health bother you most?
- What activities would you most like to participate in if your health were better?

Addressing important and more easily solved problems early in the relationship can build a patient's confidence.

Managing Limitations

Once an analysis of a patient's functional limitations has been made, the most efficacious management strategy can be selected.

1. *If the problem is caused by physical impairments or organic disease,* then medications, an operation, physical therapy, exercises, mechanical aids or prostheses (such as those prescribed by physical and occupational therapists) would all be considered. Consider two patients with treatable disease:

Patient 1
Chief problem:
Difficulty with sexual relationships.
Etiology:
Evaluation reveals erectile dysfunction due to primary testicular failure and endogenous depression.
Treatment:
He is treated with a regimen of antidepressants and testosterone injections.

Patient 2
Chief problem:
Difficulty walking short distances.
Etiology:
Angina pectoris, "controlled" by self-imposed restrictions on activity and a maximal drug regimen. No evidence of major depression or of poor compliance.
Treatment:
She is treated with a coronary artery bypass graft procedure.

2. *If the problem is primarily caused by social stress,* treatment usually consists of teaching the patient to cope with or alter the social environment. This may include obtaining financial aid or social support. Treatment might also include helping the patient deal with the effects of changes in her or his functional status on disability payments or on other family members. Consider two patients whose problems were caused primarily by social stress:

Patient 1
Chief problem:
Difficulty with sexual relationships.
Etiology:
Despite testosterone therapy, this patient continues to have erectile dysfunction on intercourse (he now has spontaneous erections). Marital stress due to a live-in mother-in-law is diagnosed.
Treatment:
Treatment consists of finding a nearby board-and-care facility for the mother-in-law and encouraging the wife's brother to participate more in his mother's care.

Patient 2
Chief problem:
Difficulty walking short distances.
Etiology:
Despite a coronary artery bypass operation, this patient is unable to increase her exercise. The problem appears to be due to fear of walking alone in her high-crime neighborhood.
Treatment:
Treatment consists of finding a younger companion to walk with patient.

3. *If the problem is caused primarily by psychological stress,* treatment usually requires development of a therapeutic alliance between doctor and patient through which a patient can gain insight into his or her personality and learn ways of coping. Below are two examples of functional problems related primarily to psychological stress.

Patient 1
Chief problem:
Difficulty with sexual relationships.
Etiology:
This patient has a long history of being unable to sustain long-term relationships. He has spontaneous erections and can have intercourse under certain circumstances.
Treatment:
Treatment consists of first providing insight as to the psychological nature of the patient's complaint—such as discussing the patient's prior history of unsatisfying relationships and the reasons for thinking that psychiatric intervention could be beneficial—and then referral to a psychiatrist.

Patient 2
Chief problem:
Difficulty walking short distances.
Etiology:
This patient had a cardiac operation three months ago and now is incapacitated by anxiety. She feels that she may "come apart" with any movement and is unresponsive to reassurance or taking mild tranquilizers. On questioning, she relates that her father died postoperatively when she was 5 years old.
Treatment:
Treatment consists of further exploring her feelings. Once she has reexamined her childhood experience, she can focus on the ways in which her current situation is different from it.

How to Set Goals

Getting patients to improve function often requires that they change specific behaviors. People are most likely to change when they are active participants in setting goals and practicing new behaviors.

In the medical setting, it is useful to distinguish between two kinds of goals: those to improve functional ability and those to prevent and treat disease. Functional improvement goals should be based primarily on a patient's expectations, such as taking a trip to Hawaii, getting training for a technical job or doing volunteer work. Goals for treating disease usually require substantial input from the physician. For example, a chronically depressed, obese patient with physical, psychological and social disabilities might tell her physician that she wanted to support herself designing and producing toys (a functional- rather than disease-related goal). She and her physician might, in addition, share the goal that she lose 100 lb over the next two years, a treatment goal that may indirectly affect functioning. These two goals need not be met simultaneously. It is often beneficial with a patient of this kind to emphasize the goal of functional improvement and to temporarily ignore the weight-loss goal. As the patient becomes involved and motivated, weight loss may be easier to achieve. Even if she does not lose weight, this patient could become a more cheerful, engaged person, an important achievement in its own right.

To be useful, goals must be specific. To set specific goals, the physician often has to ask the patient to use very precise words. The following examples illustrate this process:

Vague:
To get out more.
More specific:
To go to the movies.
Vague:
To get a job.
More specific:
To take the technical training course for a clerical job.

To increase the patient's chances of achieving a goal, it helps to include a standard of performance for each goal, as in the example below.

Goal:
To go to the movies.
Standard:
To go to the movies at least once a week.
Goal:
To take the technical training course for a clerical job.
Standard:
To pass all three parts of the course.

How to Change Behavior

In addition to setting goals, physicians may want to explore ways of establishing and reinforcing a specific behavior through stimulus control, positive or negative reinforcement, demonstration and practice.

Stimulus Control

Sometimes problem behaviors persist because they have become part of a routine, as in the following.

Problem:
Unable to walk to the bus.
Diagnosis:
Shortness of breath due to smoking and chronic obstructive pulmonary disease.
Dysfunctional behavior:
Smokes when anxious.
Behavioral treatment:
Teach relaxation techniques to use at onset of anxiety.

Positive Reinforcement

The positive reinforcement resulting from functioning better will ultimately be the most important means of motivating most patients. But specifically rewarding appropriate behaviors can be helpful. It is important to ask patients what they will find reinforcing; verbal praise or positive feedback can be reinforcement enough, but the use of rewards chosen by a patient and self-administered can also be helpful. Rewards of this kind might include nominal sums of money, a vacation or a new dress or suit. Two examples of how this process can work are given below:

Patient 1
Chief problem:
Difficulty with sexual relationships.
Diagnosis:
When the patient's physician reviews his symptom diary, it seems clear that the patient's attempts at intercourse with his wife are accompanied by frustration and criticism on her part.
Treatment:
The wife's help is enlisted to give positive reinforcement for mutual pleasurable touching of limbs and face, progressing over the succeeding weeks toward intercourse.

Patient 2
Chief problem:
Inability to walk short distances.
Diagnosis:
This patient had a cardiac operation three months ago, and is unable to resume walking despite excellent cardiac test results. Careful behavior analysis reveals that whenever the patient begins to improve her walking, she feels she must also begin strenuous housework.
Treatment:
Treatment consists of forbidding housework temporarily, while instituting a program of weekly trips to the movies if she succeeds in increasing her exercise.

Negative Reinforcement

Negative reinforcement and punishment are used to suppress undesired behaviors. Ignoring an outburst from a patient is considered negatively reinforcing, whereas speaking sternly to a patient who should quit smoking can be a form of punishment. Punishing patients is often ineffective and may have undesirable side effects. They may, for example, go to another physician.

Demonstration

Demonstration, combined with supervised practice of the desired behavior by the patient, can be a valuable tool. The "see one, do one, teach one" model by which physicians traditionally learn medical procedures is a good example of an active learning process based on demonstration. When demonstration and practice are combined with a written description of what to do, preferably accompanied by illustrations, the chances of patient success are maximized. For example:

Problem:
Decreased work performance.
Diagnosis:
Job stress due to unrealistic work goals.
Dysfunctional behavior:
Unable to say no to boss.
Behavioral treatment:
Physician and patient act as boss and employee. The patient practices

saying no when the physician-boss makes unrealistic demands, such as working during evenings when the patient is taking classes.

Problem:
Unable to walk to the bus.
Diagnosis:
Difficulty walking.
Dysfunctional behavior:
Not using cane properly.
Behavioral treatment:
Demonstration and practice of proper cane technique.

Problem:
Unable to walk to the bus.
Diagnosis:
Difficulty walking due to dyspnea.
Dysfunctional behavior:
Not using inhaler to control asthma symptoms.
Behavioral treatment:
Demonstration and practice of proper inhaler use.

Summary

The traditional history and physical examination provide only limited information about problems of physical, psychological and social function. Furthermore, traditional therapeutic techniques are not designed to foster full patient participation in improving functional status. The methods of detection, diagnosis and treatment of functional limitations discussed in this article were developed to meet the needs of the ever-increasing population of patients with chronic illnesses, among whom limitations of functioning have major long-term effects. We realize that we may be proposing an increase in the amount of time spent with each chronically ill patient. We also expect, however, that using these methods will increase the effectiveness of many physicians who are interested in devoting attention to improving patients' function. We expect that success will depend on a patient's willingness to participate, resources and a physician's ability to use our suggestions.

Medi-Cal Hospital Contracting—Did It Achieve Its Legislative Objectives?

E. RICHARD BROWN, PhD; WALTER T. PRICE, DrPH, *and* MICHAEL R. COUSINEAU, MPH, *Los Angeles*

The 1982 Medi-Cal reforms and reductions established selective contracting with hospitals for inpatient care of Medi-Cal beneficiaries. The legislation established a special negotiator and criteria to be used in selecting contract hospitals. We report the findings of a study that analyzed the characteristics of contract and noncontract hospitals in Los Angeles County to assess how well these criteria were reflected in the outcome of the contracting process. We examine issues of beneficiary access to general inpatient care and to specialized services, the efficiency of contract hospitals compared with noncontract ones and quality-related issues.

(Brown ER, Price WT, Cousineau MR: Medi-Cal hospital contracting—Did it achieve its legislative objectives? [Special Article]. West J Med 1985 Jul; 143:118-124)

In 1982, Medi-Cal (California's medicaid program) was an obvious target for state legislators who were looking for ways to reduce the state's expected $2 billion deficit. In fiscal year 1981-1982, Medi-Cal expenditures amounted to $4.8 billion, about $1 in every $8 of state expenditures, of which 57% came from state sources and 43% represented the federal contribution. Furthermore, costs were rising rapidly. Between fiscal years 1975-1976 and 1981-1982, Medi-Cal expenditures increased nearly $2 billion, with cost per service contributing 58% of the increase and number of eligible persons adding 11% to the expenditure increase.[1] Faced with these problems, leaders in the legislature—with strong support from the governor and business, labor and insurance industry groups—enacted a series of bills despite objections from the hospital industry and the medical profession.[2]

Among the far-reaching cutbacks and reforms included in Assembly Bill 799, Assembly Bill 3480, and Senate Bill 2012, probably the most significant reform was the decision to selectively contract with hospitals for inpatient care provided to Medi-Cal recipients. The objective of selective contracting was to encourage hospitals to engage in price competition for a share of the Medi-Cal business. A special negotiator was to be appointed, with unusual authority to set negotiating procedures and to conclude contracts with hospitals that would reimburse them on any basis except the old cost-based, fee-for-service system. Once this process was concluded, inpatient care to Medi-Cal recipients would be restricted to those hospitals that had signed contracts. Exceptions would be made for emergency care, care in children's and other specialized hospitals, "crossover" patients (those with Medicare and Medi-Cal) and members of prepaid health plans.

In this article we examine the results of the Medi-Cal selective contracting process with hospitals in Los Angeles County. Variables or characteristics that distinguish contract from noncontract hospitals are analyzed to assess the extent to which criteria established by the legislature were achieved in the outcome of the contracting.

Medi-Cal Hospital Contracting

The special negotiator was fully responsible for negotiating the rates, terms and conditions of the contracts. The legislation exempted the contracts from review and approval by state oversight agencies normally required for contracting services. However, the legislature mandated nine factors, in addition to price, to be considered in negotiating contracts: (1) beneficiary access; (2) utilization controls; (3) ability to render quality services efficiently and economically; (4) demonstrated ability to provide or arrange needed special services; (5) protection against fraud and abuse; (6) any other factor that would reduce costs, promote access or enhance the quality of care; (7) the capacity to provide a given tertiary service, such as specialized children's services, on a regional basis; (8) recognition of the variations in severity of illness and complexity of care, and (9) existing labor-management collective-bargaining agreements.

William Guy, former president of Blue Cross Association of Southern California, was named special negotiator and was

PSRO = Professional Standard Review Organization

soon dubbed the "Czar" because of his broad powers. In order to implement the process quickly, Guy chose to reimburse hospitals with a flat per diem rate. He also initially insisted that the contract terms remain secret as provided by the legislation. The secrecy provision, however, prevents the public from knowing even retrospectively a hospital's bid price, the final contract price or the provisions of the contract. Secrecy also makes it difficult for the public or researchers to assess how effectively the Czar fulfilled the legislated criteria to be used in hospital contracting.

Despite the secrecy surrounding the bid prices and the negotiated per diem rates, it is widely known, and was acknowledged in an interview with Guy on March 23, 1983, that acceptable bids were targeted to average about 10% below a hospital's previous average costs reimbursed by the Medi-Cal program. Thus, hospitals were expected to offer per diem rates based on their historical costs, rather than competing against other hospitals' prices. Nevertheless, there is no evidence that hospitals were told, or that they figured out, that a particular historically based price was expected of them. Because not all hospitals' bids were being accepted and because at least some hospitals that badly wanted contracts were turned down, there is every reason to believe that hospitals perceived themselves to be competing with each other—both in bid price and in services and terms offered. Hospitals throughout the state took this competition seriously after three hospitals in San Francisco that had provided inpatient care to 40% of that city's Medi-Cal recipients did not receive contracts. After filing legal challenges to their exclusion, these hospitals later were given contracts, but the effect of this early rejection had a significant impact on other hospitals in California.[3]

Negotiations were conducted individually with all hospitals in one or a few clustered Health Facilities Planning Areas (HFPAs), health planning units previously designated by the state and used by the Czar as the basic geographic contracting unit. Negotiations continued until the Czar achieved at least the targeted contracted bed capacity and negotiations were completed with all facilities especially sought by the Czar. The area was then "closed."

Negotiations began in Los Angeles County in November 1982 and lasted for seven months. Virtually all of the acute care general hospitals in Los Angeles County applied for contracts. By May 1983, contracting in 17 of the county's 19 HFPAs had been completed. Of the 136 hospitals in these closed areas, contracts were awarded to all 6 county hospitals (100%) and 78 private hospitals, the latter making up 60% of the 130 not-for-profit and investor-owned acute care general hospitals in the area.

Because the details of the contracts and of the decision-making process are still secret, the purpose of this article will be to deduce from the only information available to the public—that is, the names of hospitals with contracts and available data and characteristics of the hospitals themselves—how well the legislated criteria were implemented in awarding contracts. Because the criteria included issues of access and quality-related characteristics, this analysis will permit some assessment of the hospital services available to Medi-Cal recipients as a result of the contracts.

Methodology

Contracting and noncontracting hospitals were compared on the basis of qualitative and quantitative data that would provide a profile of a hospital's characteristics that reflect the legislative criteria and be readily available. For several legislative objectives—protection against fraud and abuse (criterion 5), presence of labor management collective bargaining contracts (9) and, of course, price—information was not available for analysis.

Data for all 136 short-term acute-care general hospitals in Los Angeles County that were eligible for contracting were obtained from the California Health Facilities Commission,[4] American Hospital Association,[5] Hospital Council of Southern California,[6] California Department of Health Services,[7] Office of the Special Negotiator,[8] the Health and Hospital Marketing Databank[9] and local Professional Standards Review Organization (PSRO) offices.* Other information pertaining to the negotiating process was obtained from interviews with current and former officials of the California Department of Health Services, the Office of the Special Negotiator and hospital administrators. Hospitals in the two HFPAs in Los Angeles County that had not yet been closed at the time of this study have been excluded from the analysis. Also excluded from the analysis were Children's Hospital of Los Angeles, psychiatric and drug rehabilitation hospitals and other specialty facilities that had been exempted from the contracting process.

Beneficiary Access

Two of the legislative criteria (1 and 6) specifically direct the Czar to consider access in negotiating contracts. In this analysis, three dimensions of access were considered: disruption of sources of inpatient care that some Medi-Cal recipients will experience because their usual hospitals did not receive contracts, a phenomenon generally termed "redirection"; availability of entry points into the inpatient system through hospital outpatient services, and availability of specialty inpatient services.

Redirection

Disruption of Medi-Cal recipients' patterns of care was measured by comparing the percentage of Medi-Cal patient-days in contract and noncontract hospitals before the contract system. It is widely assumed that preventing Medi-Cal recipients from using certain hospitals would, in itself, disrupt their patterns of care and constitute some temporary reduction in access. We examined the percentage of Medi-Cal patient-days in contract and noncontract hospitals reported to the California Health Facilities Commission (CHFC) during fiscal year 1980-1981. Of the more than one million Medi-Cal patient-days, 83.8% were provided in hospitals that subsequently received Medi-Cal contracts (Table 1).

*Dr Daniel Wilner of the Health and Hospital Marketing Databank assisted us.

Thus, some 16.2% of Medi-Cal patients in Los Angeles County had to change from their previous source of inpatient care to another hospital. The percentage of redirected patient-days in Los Angeles County is comparable with that of the state as a whole. Statewide, in areas closed by August 1983, 14% of Medi-Cal patient-days would be redirected. Although admissions or discharges would be a better measure of redirection, the CHFC reports only patient-days by a patient's source of payment. Because the data are used comparatively, patient-day provides a satisfactory, relative measure of redirection. (Statewide, 15% of discharges would be redirected, compared with 14% of patient-days.[10])

The percent of redirection varies considerably among HFPAs. The HFPAs range from no redirection in four HFPAs to 100% redirection in HFPA 937, which had a tiny Medi-Cal inpatient volume. In HFPAs with more than 10% redirection, one or two noncontract hospitals that previously had substantial Medi-Cal loads account for most of the redirection. For example, in HFPA 909, one noncontract hospital accounts for 93.3% of redirected patient-days; in HFPA 917, one hospital accounts for 84.2%, and in HFPA 927, one hospital accounts for 72.9%. In HFPA 915, three hospitals account for 83.1% of redirection. In several HFPAs, redirection is spread over several hospitals, most of which had very small shares of the Medi-Cal service volume in the HFPA.

Clearly, not granting contracts to hospitals with large shares of their HFPA's Medi-Cal volume constitutes a change in the source of inpatient care for a substantial number of persons. Although any disruption of patterns of care-seeking may be undesirable, redirecting inpatient care alone is probably the least disruptive because, compared with ambulatory care, it is infrequently used by most beneficiaries and because doctors, not patients, usually determine the hospital to which a patient is admitted. Hospital contracting applied to inpatient care only, not emergency room or outpatient department use—although a few hospitals, like Cedars-Sinai in Los Angeles, tried to redirect their Medi-Cal outpatients to contract hospitals when they did not get a contract. Except for cases such as Cedars-Sinai, the disruption is undoubtedly more problematic for admitting physicians than for their patients unless the contract hospitals are a considerable distance from a patient's home.

As is obvious from the percent of redirection resulting from the contracting outcomes, the contracting process favored hospitals that had provided greater shares of Medi-Cal inpatient days in their HFPA. County hospitals, of course, were the largest Medi-Cal providers in their areas, accounting for an average of 55.3% of the Medi-Cal inpatient days for their HFPAs. Among private hospitals, those that received contracts provided an average of 13.2% of their HFPA inpatient days compared with 7.9% for noncontract hospitals (data not shown in table form).

TABLE 1.—*Proportion of Medi-Cal Patient-Days Redirected From Noncontract Hospitals**

Area	Total Medi-Cal Patient-Days in Acute Care Hospitals, FY 1980-1981	Percent of Medi-Cal Patient-Days in Noncontract Hospitals, FY 1983-1984

Entry to Inpatient Care

For many Medi-Cal patients, emergency rooms are an entry point to hospital inpatient care as well as an important source of ambulatory care. Although finding emergency room physicians willing to admit and care for Medi-Cal patients has been a continuing problem in the Medi-Cal program, it is assumed that such patients have a better chance of being admitted when necessary if a hospital has at least a basic emergency room with a physician on duty than if it has only standby or first-aid referral services or no emergency license at all.

Of the hospitals that received contracts, 59.5% have at least basic emergency rooms (Table 2). All but two HFPAs include one or more contract hospitals with at least basic emergency services. Because Medi-Cal recipients may receive emergency inpatient and outpatient care from any licensed hospital, even in those HFPAs without basic emergency services under contract, Medi-Cal patients have

TABLE 2.—*Contract and Noncontract Hospitals by Particular Services Available**

†No Los Angeles County Department of Health Services hospital of this type.

the same access to emergency services as other insured population groups. But in one HFPA with more than 31,000 general acute care inpatient days reported in 1980-1981, Medi-Cal recipients may experience less access to inpatient care under the contract arrangements because none of the contract hospitals has a basic emergency room. Despite the generally adequate distribution of contract hospitals with emergency rooms, hospitals without even basic emergency rooms were slightly more likely to receive contracts than hospitals with them.

Specialty Inpatient Services

In addition to the criteria that specifically mentioned access, the legislature also mandated the Czar to consider a hospital's "ability to provide or arrange needed specialized services" (criterion 4), an access-related concern. Once appointed, the Czar indicated that certain services of special importance to Medi-Cal patients would be considered in the contracting process. Obstetrical care is important to the Medi-Cal population because, with the elimination of medically indigent adults from Medi-Cal and the continued ability of elderly Medi-Cal patients with Medicare to obtain inpatient care from any licensed hospital, a large proportion of Medi-Cal beneficiaries affected by selective contracting are recipients of Aid to Families With Dependent Children (AFDC) and AFDC-related medically needy persons.

Of all contract hospitals, 59.5% have obstetrical units (Table 2). Only one small HFPA is without obstetrical services in contract hospitals. The Czar estimates that the availability of such services is adequate for the Medi-Cal population's needs, but it is difficult to determine from the data whether or not they are sufficiently accessible. With these services and with emergency care, travel times to such hospitals must be taken into account as well as availability of obstetricians who accept Medi-Cal (an issue beyond the control of the Czar) to adequately evaluate access.

Of the 72 hospitals in Los Angeles County with obstetrical services, 69.4% received contracts. Thus, it appears that the contracting favored hospitals with obstetrical services and that the accessibility of these services to Medi-Cal beneficiaries is at least minimally protected.

Similarly, access to neonatal intensive care is important to Medi-Cal recipients, a disproportionately high percentage of whom are likely to have high-risk pregnancies and low-birthweight or distressed infants. Of all contract hospitals, 19.0% have a neonatal intensive care unit (NICU), compared with only 5.8% of noncontract hospitals (Table 2). Because relatively few hospitals have an NICU, there are five HFPAs without any contract or noncontract hospital that provides neonatal intensive care services. One additional HFPA includes a noncontract private hospital that provides an NICU. This pattern indicates that the Czar generally contracted with at least one hospital with an NICU in each HFPA when such hospitals were available.

Technical Complexity

The reform legislation instructed the Czar to consider a hospital's ability to provide tertiary care needed on a regional basis (criterion 7) and, in effect, include within a given area adequate provisions for more severe or complex medical problems (criterion 8). A hospital's ability to provide a complex level of care could be measured by the range or quantity of services it provides. An alternative method available in California is simply to compare hospitals on the basis of their classification by the CHFC into peer groups based on size, scope of service, service volumes and other factors.

Of the four peer group combinations considered in this study, teaching and large complex hospitals were more likely to receive contracts than the other three types (Table 3). Seven of every ten such tertiary care hospitals received contracts compared with about six of every ten among all technically less complex facilities. These more complex hospitals tended to be high-volume Medi-Cal providers so there was a strong incentive for the Czar to include them within the Medi-Cal contract system.

Four HFPAs are without any teaching or large complex hospital, either contract or noncontract. Three of these HFPAs are fairly rural areas with relatively low population density. One, however, is an urban area with a large low-income population. Though there was no tertiary care hospital in the HFPA with which the Czar could have contracted, it is a fairly narrow HFPA and Medi-Cal recipients may have adequate access to tertiary care hospitals in neighboring HFPAs. In addition to these four HFPAs that have no large technically sophisticated hospitals, another HFPA has a teaching or large complex hospital not under contract; this is a surburban area with several low-income communities, apparently none of which is near a tertiary care hospital under contract to the Medi-Cal program.

Quality of Care and Utilization Controls

The legislature directed the Czar to consider a hospital's "ability to render quality services" (criterion 3) and also specifically mentioned quality in criterion 6. In addition, Guy expressed a desire to include as many "name" hospitals as possible; these are generally large, prestigious hospitals with a broad scope of services and widely recognized as providing good quality medical care. They are also likely to have teaching programs. Quality of care is difficult to measure. It

would also have been difficult to develop a list of "name" hospitals because a survey of physicians or patients in the county was not feasible for this study.

We used two measures that are quality-*related*—delegated PSRO status and teaching status. A hospital with a utilization review mechanism approved by the Professional Standards Review Organization may be considered both as a recognized method of controlling utilization (criterion 2) and as a measure of quality, assuming the utilization review identifies and corrects grossly inappropriate medical practices. Hospitals that do not have approved internal review procedures and committees must submit to external review by the area PSRO. The value of PSRO delegation as a measure of quality is limited in part by variations in the ease with which different regional PSROs delegate responsibility to hospitals.

Utilization review has been developed mainly to control excessive utilization. This was a problem for third-party payers because fee-for-service and cost-based reimbursement systems create incentives for physicians and hospitals to do more procedures and services than may actually be needed. The new Medi-Cal per diem method of reimbursing hospitals reverses that incentive for hospitals (though not for physicians), providing incentives to do less for patients because hospitals receive the same daily rate regardless of how many services are used. Utilization review committees may concern themselves with such issues, although existing computerized monitoring systems in the Medi-Cal program cannot identify patterns of "underutilization" because they were designed for "overutilization." In any case, PSRO delegation remains a useful, albeit imperfect, measure for judging quality assurance.

Delegated PSRO status is closely associated with teaching status, which is taken as an additional quality-related factor. (Teaching status and PSRO delegation are not completely independent variables. Among the 127 hospitals for which information about both variables was available, 90.9% of the teaching hospitals have PSRO delegation compared with 56.2% of the nonteaching hospitals.) Hospitals with even modest teaching programs are more likely to attract physicians with a higher degree of technical proficiency than hospitals with no teaching component. Of course, the technical influence of teaching programs may be limited to the services included in the program, but in any given area we assumed that having a teaching program would give the hospital a favorable reputation within the medical community.

Hospitals with PSRO delegation were only slightly more likely to receive contracts than those without it. Of the 79 hospitals in Los Angeles County with delegation, 64.6% received contracts, compared with 60.4% of the 53 hospitals without delegation (Table 4). The contracting process thus resulted in a slightly higher percentage of contract hospitals having PSRO delegation (61.4%) than noncontract hospitals (57.1%).

Contract hospitals are far more likely than noncontract hospitals to have teaching programs. Of the 22 hospitals in the county with American Medical Association-approved residency programs, 20 (90.9%) received Medi-Cal contracts (Table 5). Because of the small number of teaching hospitals, they still constitute only 24.4% of all contract hospitals.

Operating Efficiency

The legislature directed the Czar to consider a hospital's ability to provide services "efficiently and economically" (criterion 3). For this study, contract and noncontract hospitals were compared on the basis of two measures of efficiency: occupancy rates, because it was assumed that hospitals with fewer empty beds would be able to spread all their fixed costs and some of their variable costs across more revenue-producing patients, and the ratio of full-time equivalent (FTE) employees to average daily census (ADC) of patients, because hospitals with lower FTE/ADC ratios use less staff per patient. To adjust for the occupancy and staffing differences related to hospital size and complexity of care, contract and noncontract hospitals were analyzed within peer groups. FTE/ADC ratios were available for only 107 of the hospitals in this study. Smaller urban and rural hospitals and "other hospitals" are especially plagued by lack of information on this variable, introducing potentially substantial errors in the findings for these peer groups and possibly the "all hospitals" figures. The more complex hospital peer groups should not be much affected.

The mean occupancy rate for contract hospitals was 55.6% compared with 49.5% for noncontract hospitals

TABLE 4.—*Contract and Noncontract Hospitals by PSRO Delegation**

PSRO Delegation	Contract Hospitals			Noncontract Hospitals (%)	All Hospitals (%)
	County	Private	Total (%)		
Delegated	6	45	51 (64.6)	28 (35.4)	79 (100.0)
Nondelegated	0	32	32 (60.4)	21 (39.6)	53 (100.0)

PSRO=Professional Standards Review Organization

Teaching Programs	Contract Hospitals			Noncontract Hospitals (%)	All Hospitals (%)
	County	Private	Total (%)		
Has program	5	15	20 (90.9)	2 (9.1)	22 (100.0)
No program	1	61	62 (57.4)	46 (42.6)	108 (100.0)

*From Guide to the Health Care Field[5] and Report to the Legislature on the Operations of the Office of Special Health Care Negotiations, Appendix K.[8]

(Table 6). Both contract and noncontract hospitals that were more complex tended to have higher occupancy rates than less complex facilities. Only among the most complex peer group did noncontract hospitals have higher occupancy on the average than contract hospitals.

Contract hospitals tend to have larger ratios of FTE employees to average daily census (Table 7). These differences remain even within three of the four peer group categories, with hospitals offering more complex care having higher FTE/ADC ratios as expected. Interestingly, moderately complex hospitals have higher mean FTE/ADC ratios than teaching and large complex hospitals. (When only private hospitals are compared, contract and noncontract teaching and large complex hospitals have essentially the same ratios, 4.9 and 4.8, respectively, suggesting that often the sicker and more difficult-to-manage cases in the county hospitals require more staffing.)

Although contract hospitals have slightly higher occupancy rates, they also may have higher FTE/ADC ratios. The occupancy rates are probably not sufficiently higher among the contract hospitals to affect their average costs per patient-day, but their FTE/ADC ratios do suggest greater expense per patient-day for this variable cost factor. Without access to the bid or final contract prices, it is impossible to know whether these differences were reflected in higher per diem bids. However, these data do suggest that if efficiency was taken into account by the Czar, other factors weighed more heavily in the award of contracts.

Commitment to the Poor

In addition to examining the Czar's fulfillment of legislated criteria, other issues aroused concern among many observers. One concern, expressed by us and other analysts, was the prospect that hospitals with a demonstrated commitment to serving the poor might not receive contracts whereas hospitals that had no such commitments might underbid to keep their options open in a time of uncertainty. The argument in support of this hypothesis was that hospitals that were heavily dependent on Medi-Cal revenues would have to bid their average costs because Medi-Cal patients made up such a large share of their total patient-days, and that hospitals with a low volume of Medi-Cal service could bid their marginal costs (which would be lower than average costs) because Medi-Cal charges were a relatively insignificant part of their revenue. The fear was that hospitals that had shown a commitment to serving the poor but that did not receive contracts might become so financially distressed that they would be forced to close, depriving the poor and the community of socially useful institutions. Guy did not alleviate this concern when he announced early in the negotiating process that he would treat every hospital as a competitor in an economic market and not as a social institution that must be preserved.

A hospital's commitment to serving the poor was measured by several factors: the percentage of its inpatient and outpatient revenues derived from serving Medi-Cal patients; the ratio of outpatient visits to inpatient days, because low-income persons are more dependent on clinics and hospitals for ambulatory care than are the more affluent and adequately insured population, and whether the hospital reported an operating deficit in fiscal year 1980-1981. Operating deficits are associated with providing uncompensated care to uninsured and poor patients and with serving a greater proportion of Medi-Cal recipients because Medi-Cal paid a lower percentage of all costs than did other third-party payers. In 1979, Blue Cross and commercial insurance companies reimbursed hospitals 12% more than their "full financial requirements" (including the actual costs of providing care plus working capital and capital replacement costs), Medicare reimbursed them 4% less than their full costs and Medi-Cal paid them 18% less than their full costs, according to a study by the CHFC.[11]

County hospitals, as expected, have the greatest commitment to serving the poor as shown by their great dependence on Medi-Cal inpatient and outpatient revenues (Table 8). Similarly, they have a high average ratio of outpatient visits to inpatient days. All six county hospitals reported an operating deficit in 1980-1981, as they do every year.

Private hospitals that received contracts were substantially more dependent on Medi-Cal for their inpatient revenues than noncontract hospitals, and they were slightly more dependent on Medi-Cal for their outpatient revenues as well, although they had slightly lower ratios of outpatient visits to inpatient days. More than a third of all private contract hospitals reported operating deficits in 1980-1981 compared with only a fourth of their noncontract counterparts.

TABLE 6.—*Occupancy Rate of Contract and Noncontract Hospitals by Peer Group**

Peer Group	Contract Hospitals (%)	Noncontract Hospitals (%)
All hospitals	84 (55.6)	52 (49.5)
Teaching and large complex hospitals	23 (64.9)	10 (68.7)
Moderately complex hospitals	22 (55.4)	17 (53.4)
Smaller urban and rural hospitals	29 (50.2)	18 (43.0)
Other hospitals	10 (50.0)	7 (29.2)

Discussion and Conclusion

The analysis of the outcome of the hospital contracting process in Los Angeles County suggests that the criteria established by the legislature were substantially achieved. First, access by Medi-Cal beneficiaries to inpatient hospital care seems to be reasonably well protected by selective contracting. A small percentage (16.2%) of Medi-Cal patient days must be redirected from noncontract hospitals to facilities with contracts, though the percentage of redirection within HFPAs varies considerably. Access to emergency

TABLE 8.—*Commitment to Serve the Poor by Contract and Noncontract Hospitals and Ownership**

Commitment to Serve the Poor	Contract Hospitals		Noncontract Hospitals	Number
	County	Private		
Mean percent inpatient revenue from Medi-Cal (%) . . .	37.9	13.4	8.3	128
Mean percent outpatient revenue from Medi-Cal (%) . .	11.0	3.3	3.0	136
Mean ratio of outpatient visits per inpatient day (%) . .	2.0	0.9	1.3	128
Percent hospitals with operating deficit reported in 1980-1981 (%)	100.0	35.9	26.9	136

*From Individual Hospital Data for California, 1980-1981,[4] and Report to the Legislature on the Operations of the Office of Special Health Care Negotiations, Appendix K.[8]

room services through which Medi-Cal recipients might be admitted to hospital for nonemergency problems seems generally adequate, although two HFPAs are without any contract hospital that has at least a basic emergency room. Only one HFPA has no obstetric inpatient services under contract. Access to neonatal intensive care services is more restricted because relatively few hospitals have such services. Two HFPAs seem deficient in the availability of technically sophisticated inpatient care, though one of the HFPAs is a rural area that is not far from other areas with contract hospitals.

Second, technically more sophisticated hospitals, especially those with teaching programs, were more likely to receive contracts. Whether these are truly higher quality hospitals is difficult to judge although our indicators—having a teaching program and PSRO delegation to an in-hospital utilization review committee—suggest that contract hospitals are, at the very least, not inferior.

Third, contract hospitals tend to have higher occupancy rates (except among teaching and large complex hospitals), but they also have higher ratios of full-time staff to average daily census. Although the Czar may have taken these or other measures of efficiency into account, other factors obviously carried more weight in the contracting process.

Fourth, hospitals with a demonstrated commitment to serving the poor tended to be more successful in winning contracts. In addition to the county hospitals, private hospitals that were more dependent on Medi-Cal inpatient revenues were more likely to receive contracts than hospitals that derived smaller percentages of their revenue from Medi-Cal. Similarly, hospitals that had reported operating deficits in fiscal year 1980-1981 were also more likely to receive contracts.

The contracting process seems to have worked well in Los Angeles County. The legislature's criteria were substantially met, Medi-Cal beneficiaries had access to inpatient care in general and to specialized and technically complex services in facilities of at least average quality. In general, hospitals with a demonstrated commitment to serving the poor are well represented among contract hospitals. It seems clear that the Czar considered hospital characteristics in a manner consistent with the legislature's criteria.

Some caution is warranted in concluding that Medi-Cal selective contracting is an unqualified success. First, this study has some methodologic limitations. The analysis has been made without measures of performance for several legislated criteria—protection against fraud and abuse, presence of labor-management collective bargaining contracts and price—and has used very imperfect measures of another criterion—quality. In addition, the analysis is based on hospitals only in Los Angeles County; the results of the contracting process may be somewhat different in other counties.

Second, this analysis focuses only on the outcome of the negotiating process—which hospitals got contracts and which did not—and characteristics of the Medi-Cal inpatient hospital system in place at the conclusion of the contracting process. We do not yet have any evidence concerning the long-term effect of contracting on either Medi-Cal recipients or on hospitals. It may work as it has been optimistically envisioned. Medi-Cal patients may not suffer any significant loss of access. Medi-Cal hospitals may make up in increased volumes for the (on average) lower patient-day revenues they now receive from Medi-Cal and simply eliminate unnecessary services they formerly provided to patients. On the other hand, contracting may develop into the more pessimistic scenario that many have predicted. Medi-Cal recipients' actual access to health care may be restricted considerably more than this analysis suggests. Contract hospitals with a heavy Medi-Cal load may receive substantially less revenue than their costs, have greater difficulties obtaining capital and end up providing second-class care to Medi-Cal recipients or closing their doors altogether.[2,3]

Our findings support the conclusion that the special negotiator substantially implemented the criteria for Medi-Cal selective contracting with hospitals established by the legislature, as represented by the outcome of contract negotiations in Los Angeles. It is too early, however, to judge the actual immediate or long-term consequences of the program on beneficiaries or hospitals.

BALANCED CALCIUM CHANNEL BLOCKADE!

CARDIZEM®
(diltiazem HCl)

balances potent coronary vasodilation with a low incidence of side effects

Low incidence of side effects
CARDIZEM® (diltiazem HCl) produces an incidence of adverse reactions not greater than that reported with placebo therapy, thus contributing to the patient's sense of well-being.

Reduces angina attack frequency*
42% to 46% decrease reported in multicenter study.[1]

Increases exercise tolerance*
In Bruce exercise test,[2] control patients averaged 8.0 minutes to onset of pain; Cardizem patients averaged 9.8 minutes ($P<.005$).

*Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm and in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

CARDIZEM®
(diltiazem HCl)

THE BALANCED CALCIUM CHANNEL BLOCKER

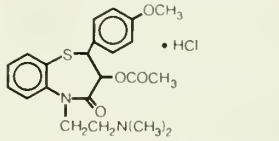
Please see full prescribing information on following page.

PROFESSIONAL USE INFORMATION

cardizem®
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM® (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy) -5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem hydrochloride for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanisms of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance, probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate-blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina. CARDIZEM has been effective in controlled trials in reducing angina frequency and increasing exercise tolerance.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, patients receiving CARDIZEM have exhibited reversible acute hepatic injury as evidenced by moderate to extreme elevations of liver enzymes. (See PRECAUTIONS and ADVERSE REACTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS).

Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities. In healthy volunteers, diltiazem has been shown to increase serum digoxin levels up to 20%.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%), AV block (1.1%). In addition, the following events were reported infrequently (less than 1%) with the order of presentation corresponding to the relative frequency of occurrence.

Cardiovascular:	Flushing, arrhythmia, hypotension, bradycardia, palpitations, congestive heart failure, syncope.
Nervous System:	Paresthesia, nervousness, somnolence, tremor, insomnia, hallucinations, and amnesia.
Gastrointestinal:	Constipation, dyspepsia, diarrhea, vomiting, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH.
Dermatologic:	Pruritus, petechiae, urticaria, photosensitivity.
Other:	Polyuria, nocturia.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: erythema multiforme; leukopenia; and extreme elevations of alkaline phosphatase, SGOT, SGPT, LOH, and CPK. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experience with oral diltiazem has been limited. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral/LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LO_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. Although individual patients may respond to any dosage level, the average optimum dosage range appears to be 180 to 240 mg/day. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents:

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

Cardizem 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1771-49). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47) and in Unit Dose Identification Paks of 100 (NDC DD88-1772-49). Each yellow tablet is engraved with MARIDN on one side and 1772 on the other.

UTAH

This listing of continuing medical education courses in Utah is compiled and edited by the CME office of the Utah State Medical Association. All courses listed have been certified by CME accredited institutions as meeting the criteria for Category 1 of the Physician's Recognition Award of the American Medical Association. They also must meet the definition of Utah Approved CME Credit for the purpose of medical license reregistration in Utah. Accredited institutions wishing to list AMA Category 1/Utah Approved CME courses here should send information at least two months in advance to the Office of Continuing Medical Education, 540 East Fifth South, Salt Lake City, Utah 84102; or phone (801) 355-5290. For information on CME accreditation or on the CME requirements of the Utah Physicians' Licensing Board, please write the CME office at the above address.

NOTE: Course information in the following listing is subject to change on occasion. Check with the sponsoring institution or the CME office for current details.

SPONSORS OF COURSES—ABBREVIATIONS

AF: Arthritis Foundation, 1174 East 2700 South, Salt Lake City 84117. (801) 466-9389.

CH: Castleview Hospital (formerly Carbon Hospital), RFD 2, Box 46, Price, UT 84501. (801) 637-4800.

CWH: Cottonwood Hospital, 5770 South 300 East, Salt Lake City 84101. (801) 262-3461.

FHP: Family Health Program/Utah, 323 South Sixth East, Salt Lake City 84102. (801) 335-1234. Contact: Kay Schultz for course information.

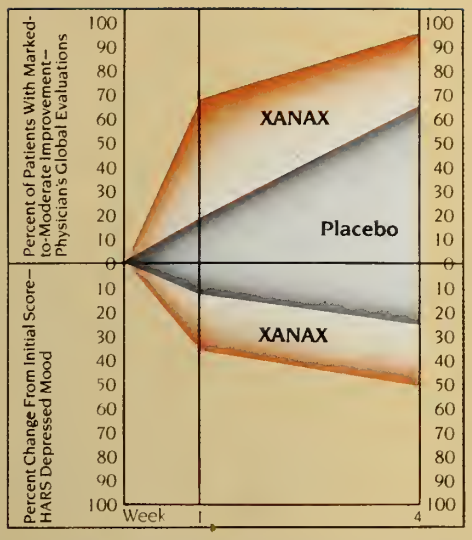
In 7 of 10
anxious
geriatrics...
Anxiety and
depressive
symptoms
go hand
in hand.

Xanax rapidly relieves anxiety with depressive symptoms.



In a recent clinical study[1] of 83 geriatric patients with clinical anxiety, 73% were diagnosed as having symptoms of depressed mood.

XANAX is well suited for therapy because it demonstrates greater efficacy than placebo in reducing the Hamilton Anxiety Rating Scale Total Score and individual items including depressed mood (see Figure).

With clinical advantages for geriatric patients.

- **Rapidly relieves** the symptoms of anxiety
- **Rapidly relieves** associated depressed mood
- **Well tolerated**—mild, transient drowsiness, the most commonly reported side effect the first week of therapy, shows a marked decrease thereafter and is not significantly different from that of placebo
- **Does not cause** cardiotoxicity
- **Specific geriatric dosage**—0.25 mg, two or three times daily

1 Cohn JB Double-blind safety and efficacy comparison of alprazolam and placebo in the treatment of anxiety in geriatric patients. *Curr Ther Res* 1984 35(1):100-112

Xanax® 0.25 mg Tablets
alprazolam IV

©1984 The Upjohn Company

Upjohn THE UPJOHN COMPANY
Kalamazoo, Michigan 49001 USA

Please see next page for brief summary of prescribing information.

XANAX® Tablets
(alprazolam) ℞

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation. (See Drug Interaction section.) Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage. (See Dosage and Administration.) Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions.* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility* No carcinogenic potential or impairment of fertility in rats *Pregnancy* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity *Labor and Delivery* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse *Pediatric Use* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation.

Cardiovascular Tachycardia/palpitations, and hypotension

Sensory Blurred vision.

Musculoskeletal: Rigidity and tremor

Cutaneous. Dermatitis/allergy

Other side effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class.* XANAX is a controlled substance and has been assigned to schedule IV

DOSAGE AND ADMINISTRATION
The usual starting dose is 0.25 to 0.5 mg. t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily Reduce dosage gradually when terminating therapy, by no more than one milligram every three days.

CAUTION FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION B-3-S

Physicians

The Perfect Practice Is One That Lets You Practice

At Westworld Community Healthcare, Inc., physicians have something very special: **Time.** Time to devote to their practices, and to their patients. And they have the time because we handle all the business details their practices demand.

The goal of every Westworld Hospital is to help our physicians be as productive as they can possibly be. We handle all the paperwork and administrative details, and assist in everything from setting up medical offices to providing staffing and equipment. What's more, we provide an excellent compensation package - competitive with private practice - along with incentive for additional income. And since our commitment is to meet the unique health care needs of rural America, there is no competing with hundreds of other practitioners for patients.

All of these advantages mean **security** for the Westworld physician. If your commitment is to the highest standards in patient care, and if a rural environment sounds inviting to you, investigate Westworld Community Healthcare. We have a variety of attractive practice opportunities in rural America. Call collect now for more information, or send your curriculum vitae to: **Mr. Joel Feinstein, Dept. PH-3, (714) 768-2981, Westworld Community Healthcare, Inc., 83832 Rockfield Rd., Lake Forest, CA 92630-2880.** We are an equal opportunity employer m/f.

WCH Westworld Community Healthcare, Inc.

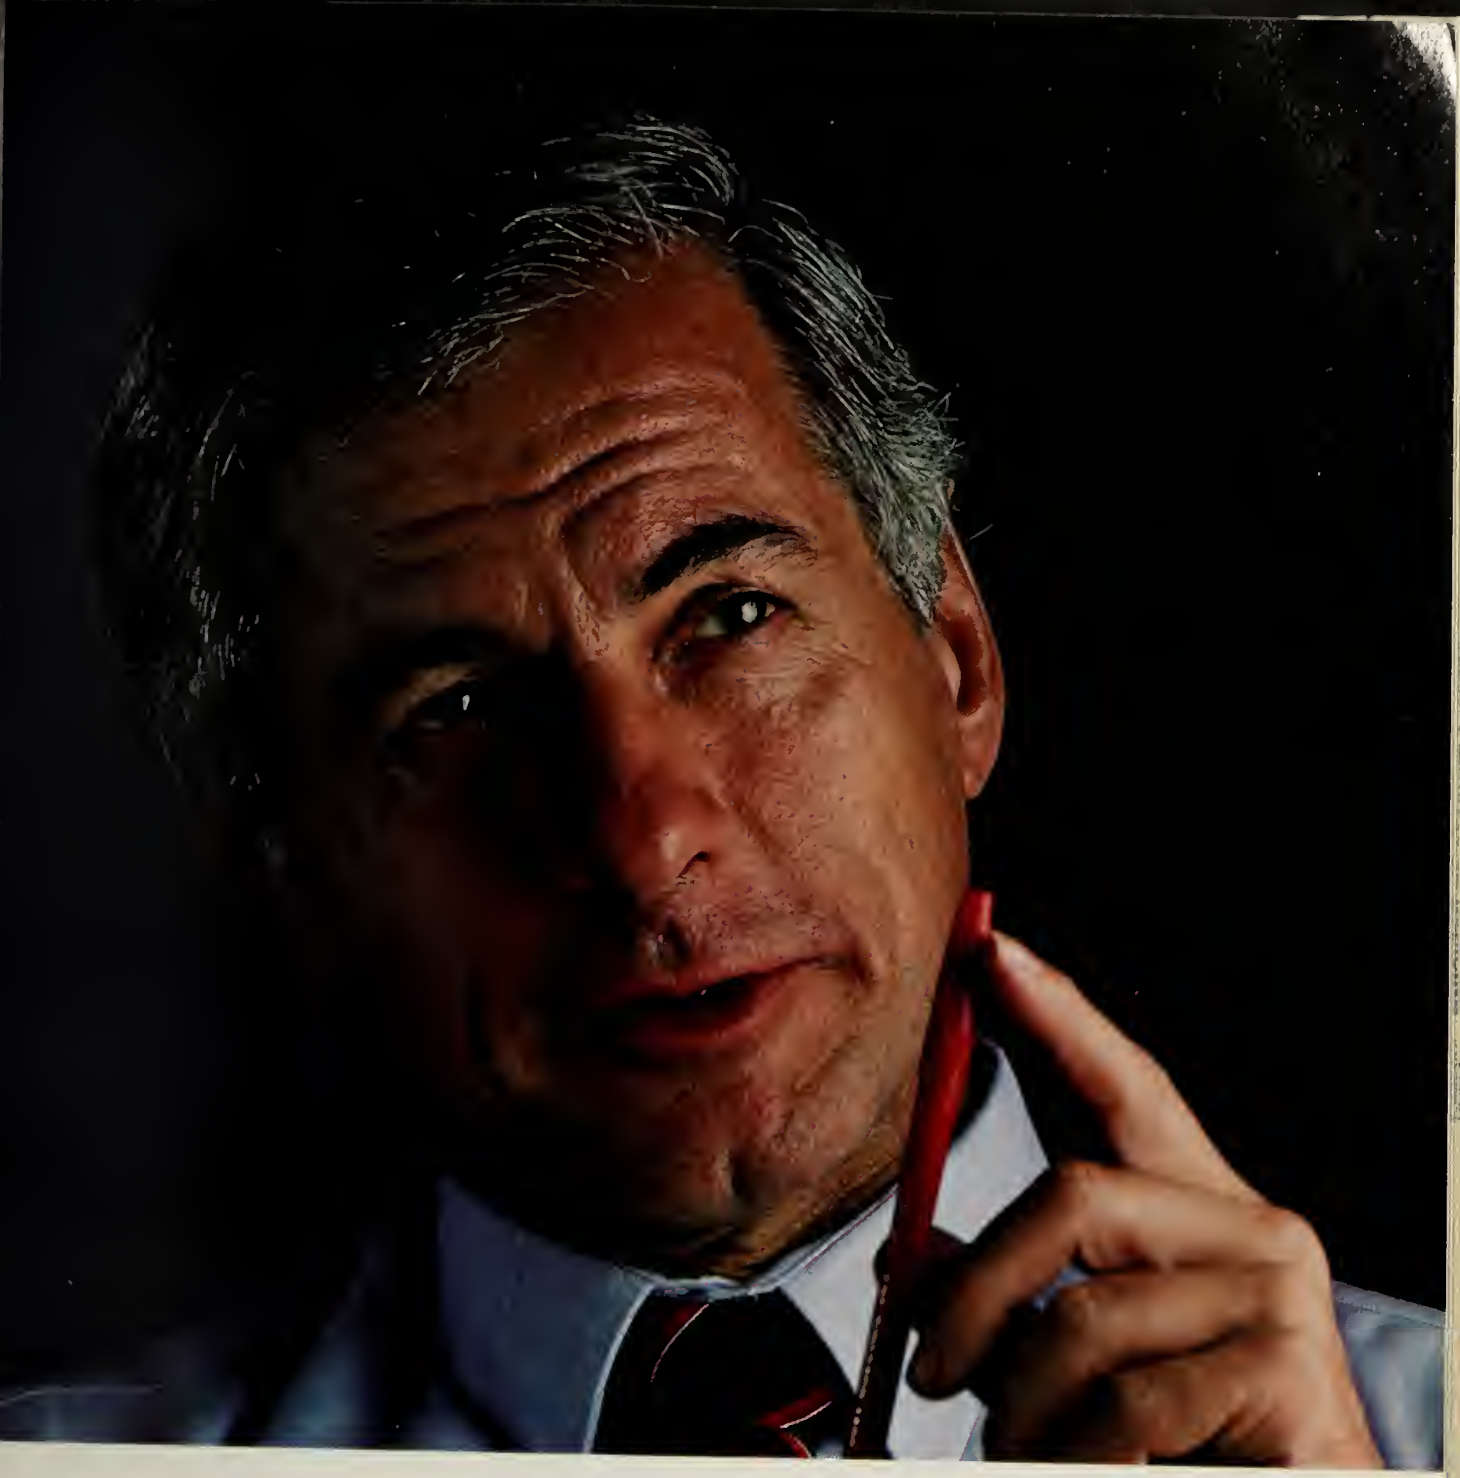
RADIOLOGIST SEEKS POSITION—41-year-old experienced Radiologist (academics and private practice) seeks multispecialty group, solo-type practice, or imaging center. Reply Box 6486, Western Journal of Medicine, 44 Gough St., San Francisco, CA 94103.



"When the Ayerst rep told me it costs about 45¢ a day, I said you can stop right there."

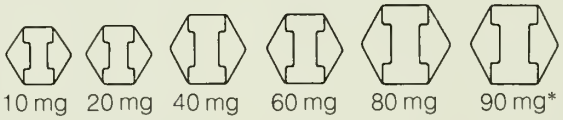
Most doctors are pleasantly surprised to learn that the average cost of daily therapy with the world's most widely used beta blocker is so little, not much more than the cost of a daily newspaper.

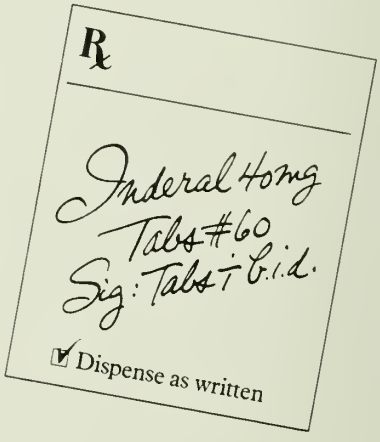
When it's INDERAL (propranolol hydrochloride) tablets you want for your hypertension patients, remember to specify Dispense As Written (DAW) or Do Not Substitute on your prescriptions. That way, you can always be assured they'll get INDERAL®. Please see next page for brief summary of prescribing information.

INDERAL®
(PROPRANOLOL HCl)
Small price to pay.

"When the Ayerst rep told me it costs about 45¢ a day, I said you can stop right there."

INDERAL® TABLETS
(PROPRANOLOL HCl)





BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

INDERAL® (propranolol hydrochloride) Tablets

CONTRAINDICATIONS

INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma, 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS

CARDIAC FAILURE. Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY. The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA. Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS. Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS

General. Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL (propranolol hydrochloride) may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests. Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS. Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility. Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy. Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia, congestive heart failure, intensification of AV block, hypotension, paresthesia of hands, thrombocytopenic purpura, arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Lightheadedness, mental depression manifested by insomnia, lassitude, weakness, fatigue, reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

New Prescribing Information

Now—Easier to remember... easier to prescribe

In place of Limbitrol 5–12.5 write:

Limbitrol®

Each tablet contains 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt) Ⓒ IV

In place of Limbitrol 10–25 write:

Limbitrol® DS

Each tablet contains 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) Ⓒ IV

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of moderate to severe depression associated with moderate to severe anxiety

Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.

Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.) Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

Usage in Pregnancy: **Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage, withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).

Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated, sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12. In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.

Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.

The following list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs:

Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.

Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.

Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.

Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.

Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.

Endocrine: Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female, elevation and lowering of blood sugar levels, and syndrome of inappropriate ADH (antidiuretic hormone) secretion.

Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.

Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single *h.s.* dose may suffice for some patients. Lower dosages are recommended for the elderly.

Limbitrol DS (double strength) Tablets, initial dosage of three or four tablets daily in divided doses, increased to six tablets or decreased to two tablets daily as required. Limbitrol Tablets, initial dosage of three or four tablets daily in divided doses, for patients who do not tolerate higher doses.

How Supplied: *Double strength (DS) Tablets*, white, film-coated, each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt), and *Tablets*, blue, film-coated, each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500, Tel-E-Dose® packages of 100, Prescription Paks of 50.

DALMANE®
flurazepam HCl/Roche ®
sleep that satisfies
15-mg/30-mg capsules

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening, in patients with recurring insomnia or poor sleeping habits, in acute or chronic medical situations requiring restful sleep. Objective sleep laboratory data have shown effectiveness for at least 28 consecutive nights of administration. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended. Repeated therapy should only be undertaken with appropriate patient evaluation.

Contraindications: Known hypersensitivity to flurazepam HCl; pregnancy. Benzodiazepines may cause fetal damage when administered during pregnancy. Several studies suggest an increased risk of congenital malformations associated with benzadiazepine use during the first trimester. Warn patients of the potential risks to the fetus should the possibility of becoming pregnant exist while receiving flurazepam. Instruct patients to discontinue drug prior to becoming pregnant. Consider the possibility of pregnancy prior to instituting therapy.

Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. An additive effect may occur if alcohol is consumed the day following use for nighttime sedation. This potential may exist for several days following discontinuation. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Potential impairment of performance of such activities may occur the day following ingestion. Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, abrupt discontinuation should be avoided with gradual tapering of dosage for those patients on medication for a prolonged period of time. Use caution in administering to addiction-prone individuals or those who might increase dosage.

Precautions: In elderly and debilitated patients, it is recommended that the dosage be limited to 15 mg to reduce risk of oversedation, dizziness, confusion and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in severely depressed patients, or in those with latent depression or suicidal tendencies, or in those with impaired renal or hepatic function.

Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, and elevated SGOT, SGPT, total and direct bilirubins, and alkaline phosphatase, and paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity.

Dosage: Individualize for maximum beneficial effect. *Adults:* 30 mg usual dosage; 15 mg may suffice in some patients. *Elderly or debilitated patients:* 15 mg recommended initially until response is determined.

Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

Advertisements—The journal is published the first week of the month. Advertising copy must be received no later than the first of the month preceding issue. Advertising rates will be sent on request. Acceptance of advertising is contingent upon approval by the Advertising Committee. *The journal reserves the right to reject any advertisement.*

SUBSCRIPTION INFORMATION

The subscription price per year is $20 in the United States and Canada (US funds); $30 in all other countries. Single copies are $4.50 (which includes postage and handling). Address all subscription communications to THE WESTERN JOURNAL OF MEDICINE Circulation, 44 Gough Street, San Francisco, CA 94103-1233 • Tel: (415) 863-5522.

Allow six weeks for subscriptions to begin. Past issues must be bought individually. So long as reserve stocks are available, missing issue requests from subscribers are honored for up to six months after the issue date. Thereafter, the single copy rate of $4.50 is applicable for each issue available.

Change of Address—Requests for change of address should give both the old and new address. Allow six weeks for changeover.

SUBMITTING MANUSCRIPTS

"Information for Authors"—A complete guide to manuscript submission and journal style is available on request and also appears in January and July.

Author Responsibility—Authors are responsible for all statements, conclusions and methods of presenting subjects. Articles are accepted on condition that they are contributed solely to this journal.

Manuscripts—Ordinarily manuscripts should not exceed 3,000 words (less than 15 typed double-spaced pages). The original manuscript and two copies should be submitted, typed double-spaced throughout. If photographic illustrations are desired, three sets of clear, unmounted black and white glossy prints should be supplied. For line drawings, original artwork or glossy prints are acceptable. Tables should be typed on separate sheets of paper.

Clinical Investigation—Papers that authors wish considered for the Clinical Investigation section should be so designated in the transmittal letter.

New Motrin® 800 TABLETS mg

ibuprofen

a stronger reason to prescribe Motrin Tablets

© 1985 The Upjohn Company

New Motrin® 800 TABLETS mg
ibuprofen

Extra-Strength Motrin Tablets— a convenient way to tap the full potential of Motrin:

The newest strength of *Motrin* Tablets

makes treatment easier for arthritis patients who need the doses that provide higher levels of anti-inflammatory activity as well as potent analgesia...just 1 tablet t.i.d. provides 2400 mg/day.

expands the dosage convenience of MOTRIN Tablets—makes it even easier to adjust the dosage of MOTRIN to each patient's needs...the new dosage range of up to 3200 mg/day can be achieved on a q.i.d. regimen. Gastroscopic studies at varying doses show an increased tendency toward gastric irritation at higher doses. However, at comparable doses, gastric irritation is about half that seen with aspirin.

provides economy...patients should pay less for MOTRIN Tablets than comparable dosages of Clinoril, Feldene, or Naprosyn.

provides, above all, the experience-proven efficacy and safety profile of *Motrin.* MOTRIN continues to be America's most often prescribed nonsteroidal anti-inflammatory agent.

Please turn the page for a brief summary of prescribing information.

Upjohn

The Upjohn Company, Kalamazoo, Michigan 49001

Motrin® Tablets
(ibuprofen)

Indications and Usage: Treatment of signs and symptoms of rheumatoid arthritis and osteoarthritis. Relief of mild to moderate pain and primary dysmenorrhea. Safety and efficacy in children are not established.

Contraindications: Anaphylactoid reactions have occurred in individuals hypersensitive to MOTRIN or with the syndrome of nasal polyps, angioedema and bronchospastic reactivity to aspirin or other nonsteroidal anti-inflammatory agents.

Warnings: Peptic ulceration and GI bleeding, sometimes severe, have been reported. Ulceration, perforation and bleeding may end fatally. An association has not been established. Use MOTRIN under close supervision in patients with a history of upper gastrointestinal tract disease, after consulting ADVERSE REACTIONS. In patients with active peptic ulcer and active rheumatoid arthritis, try nonulcerogenic drugs, such as gold. If MOTRIN is used, observe the patient closely for signs of ulcer perforation or GI bleeding.

Chronic studies in rats and monkeys have shown mild renal toxicity with papillary edema and necrosis. Renal papillary necrosis has rarely been shown in humans treated with MOTRIN.

Precautions: Blurred and/or diminished vision, scotomata, and/or changes in color vision have been reported. If these develop, discontinue MOTRIN and the patient should have an ophthalmologic examination, including central visual fields and color vision testing.

Fluid retention and edema have been associated with MOTRIN; use with caution in patients with a history of cardiac decompensation or hypertension. In patients with renal impairment, reduced dosage may be necessary. Prospective studies of MOTRIN safety in patients with chronic renal failure have not been done.

MOTRIN can inhibit **platelet aggregation** and prolong bleeding time. Use with caution in persons with intrinsic coagulation defects and on anticoagulant therapy.

Patients should report signs or symptoms of **gastrointestinal ulceration** or bleeding, blurred vision, skin rash, weight gain, or edema. Patients on prolonged **corticosteroid therapy** should have therapy tapered slowly when MOTRIN is added.

The antipyretic, anti-inflammatory activity of MOTRIN may mask inflammation and fever.

As with other nonsteroidal anti-inflammatory drugs, borderline elevations of liver tests may occur in up to 15% of patients. These abnormalities may progress, may remain essentially unchanged, or may be transient with continued therapy. Meaningful elevations of SGPT or SGOT (AST) occurred in controlled clinical trials in less than 1% of patients. Severe hepatic reactions, including jaundice and cases of fatal hepatitis, have been reported with ibuprofen as with other nonsteroidal anti-inflammatory drugs. If liver disease develops or if systemic manifestations occur (eg, eosinophilia, rash, etc.), MOTRIN should be discontinued.

In cross-study comparisons with 1200 mg to 3200 mg daily for several weeks, a slight dose-response decrease in hemoglobin/hematocrit was noted. The total decrease in hemoglobin usually does not exceed 1 gram.

Drug interactions—*Aspirin:* used concomitantly may decrease MOTRIN blood levels.
Coumarin: bleeding has been reported in patients taking MOTRIN and coumarin.

Pregnancy and nursing mothers: MOTRIN should not be taken during pregnancy or by nursing mothers.

Adverse Reactions: The most frequent type of adverse reaction occurring with MOTRIN is gastrointestinal, of which one or more occurred in 4% to 16% of the patients. Reported side effects were higher at 3200 than at 2400 mg/day or less.

Incidence Greater Than 1% (but less than 3%)—Probable Causal Relationship
Gastrointestinal: Nausea,* epigastric pain,* heartburn,* diarrhea, abdominal distress, nausea and vomiting, indigestion, constipation, abdominal cramps or pain, fullness of GI tract (bloating and flatulence); **Central Nervous System:** Dizziness,* headache, nervousness; **Dermatologic:** Rash* (including maculopapular type), pruritus; **Special Senses:** Tinnitus; **Metabolic/Endocrine:** Decreased appetite; **Cardiovascular:** Edema, fluid retention (generally responds promptly to drug discontinuation; see PRECAUTIONS).

Incidence Less Than 1%—Probable Causal Relationship*
Gastrointestinal: Gastric or duodenal ulcer with bleeding and/or perforation, gastrointestinal hemorrhage, melena, gastritis, hepatitis, jaundice, abnormal liver function tests; **Central Nervous System:** Depression, insomnia, confusion, emotional lability, somnolence, aseptic meningitis with fever and coma; **Dermatologic:** Vesiculobullous eruptions, urticaria, erythema multiforme, Stevens-Johnson syndrome, alopecia; **Special Senses:** Hearing loss, amblyopia (blurred and/or diminished vision, scotomata, and/or changes in color vision) (see PRECAUTIONS); **Hematologic:** Neutropenia, agranulocytosis, aplastic anemia, hemolytic anemia (sometimes Coombs positive), thrombocytopenia with or without purpura, eosinophilia, decreases in hemoglobin and hematocrit (see PRECAUTIONS); **Cardiovascular:** Congestive heart failure in patients with marginal cardiac function, elevated blood pressure, palpitations; **Allergic:** Syndrome of abdominal pain, fever, chills, nausea and vomiting; anaphylaxis; bronchospasm (see CONTRAINDICATIONS); **Renal:** Acute renal failure in patients with pre-existing significantly impaired renal function, decreased creatinine clearance, polyuria, azotemia, cystitis, hematuria; **Miscellaneous:** Dry eyes and mouth, gingival ulcer, rhinitis.

Incidence Less Than 1%—Causal Relationship Unknown*
Gastrointestinal: Pancreatitis; **Central Nervous System:** Paresthesias, hallucinations, dream abnormalities, pseudotumor cerebri; **Dermatologic:** Toxic epidermal necrolysis, photoallergic skin reactions; **Special Senses:** Conjunctivitis, diplopia, optic neuritis, cataracts; **Hematologic:** Bleeding episodes (eg, epistaxis, menorrhagia); **Metabolic/Endocrine:** Gynecomastia, hypoglycemic reaction, acidosis; **Cardiovascular:** Arrhythmias (sinus tachycardia, sinus bradycardia); **Allergic:** Serum sickness, lupus erythematosus syndrome, Henoch-Schönlein vasculitis, angioedema; **Renal:** Renal papillary necrosis.

Overdosage: In cases of acute overdosage, the stomach should be emptied. The drug is acidic and excreted in the urine so alkaline diuresis may be beneficial.

Dosage and Administration: Do not exceed 3200 mg/day.

Rheumatoid arthritis and osteoarthritis: Suggested dosage is 1200 to 3200 mg per day (400, 600 or 800 mg t.i.d. or q.i.d.). The smallest effective dosage should be used. Mild to moderate pain: 400 mg every 4 to 6 hours as necessary.

How Supplied:

MOTRIN Tablets, 400 mg (orange)	MOTRIN Tablets, 600 mg (peach)	MOTRIN Tablets, 800 mg (apricot)
Bottles of 500	Bottles of 500	Bottles of 100
Unit-dose package of 100	Unit-dose package of 100	Bottles of 500
Unit of Use bottles of 100	Unit of Use bottles of 100	

Caution: Federal law prohibits dispensing without prescription. *For additional product information, see your Upjohn representative or consult the package insert.*

*Reactions occurring in 3% to 9% of patients treated with MOTRIN. (Those reactions occurring in less than 3% of the patients are unmarked.)

**Reactions are classified under *"Probable Causal Relationship (PCR)"* if there has been one positive rechallenge or if three or more cases occur which might be causally related. Reactions are classified under *"Causal Relationship Unknown"* if seven or more events have been reported but the criteria for PCR have not been met.

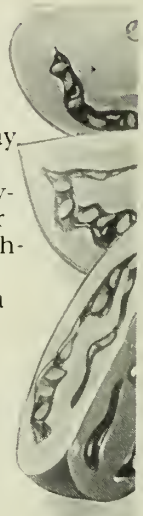
A defense against cancer can be cooked up in your kitchen.



There is evidence that diet and cancer are related. Some foods may promote cancer, while others may protect you from it.

Foods related to lowering the risk of cancer of the larynx and esophagus all have high amounts of carotene, a form of Vitamin A which is in cantaloupes, peaches, broccoli, spinach, all dark green leafy vegetables, sweet potatoes, carrots, pumpkin, winter squash, and tomatoes, citrus fruits and brussels sprouts.

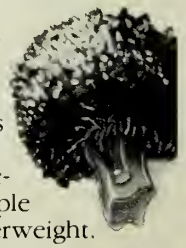
Foods that may help reduce the risk of gastrointestinal and respiratory tract cancer are cabbage, broccoli, brussels sprouts, kohlrabi, cauliflower.

Fruits, vegetables and whole-grain cereals such as oatmeal, bran and wheat may help lower the risk of colorectal cancer.

Foods high in fats, salt- or nitrite-cured foods such as ham, and fish and types of sausages smoked by traditional methods should be eaten in moderation.

Be moderate in consumption of alcohol also.

A good rule of thumb is cut down on fat and don't be fat. Weight reduction may lower cancer risk. Our 12-year study of nearly a million Americans uncovered high cancer risks particularly among people 40% or more overweight.

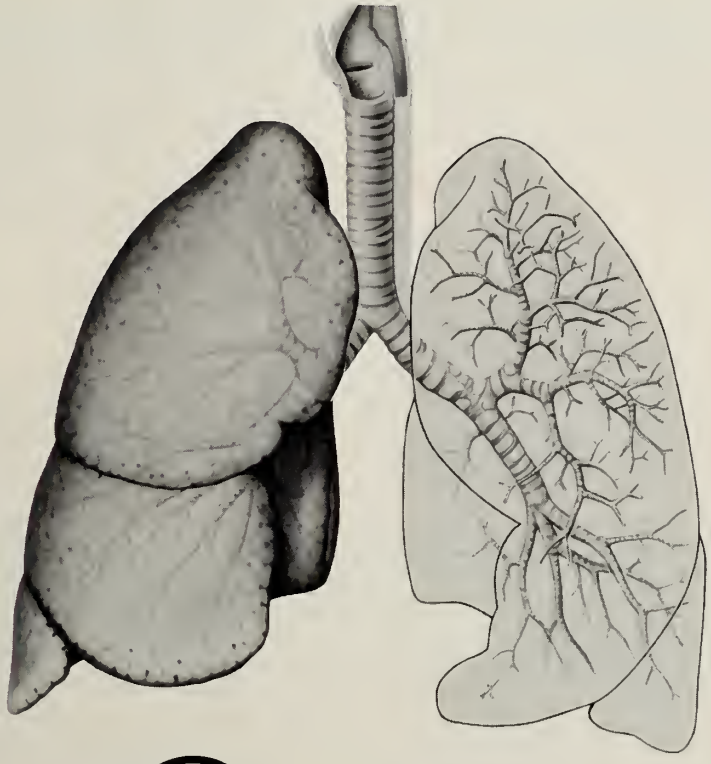


Now, more than ever, we know you can cook up your own defense against cancer. So eat healthy and be healthy.

No one faces cancer alone.

AMERICAN CANCER SOCIETY®

Consider the causative organisms...



Ceclor®
cefaclor
250-mg Pulvules® t.i.d.

offers effectiveness against the major causes of bacterial bronchitis

H. influenzae, *H. influenzae*, *S. pneumoniae*, *S. pyogenes*
(ampicillin-susceptible) (ampicillin-resistant)

Brief Summary. Consult the package literature for prescribing information.

Indications and Usage: Ceclor* (cefaclor, Lilly) is indicated in the treatment of the following infections when caused by susceptible strains of the designated microorganisms

Lower respiratory infections, including pneumonia caused by *Streptococcus pneumoniae (Diplococcus pneumoniae), Haemophilus influenzae*, and *S. pyogenes* (group A beta-hemolytic streptococci)

Appropriate culture and susceptibility studies should be performed to determine susceptibility of the causative organism to Ceclor

Contraindication: Ceclor is contraindicated in patients with known allergy to the cephalosporin group of antibiotics

Warnings: IN PENICILLIN-SENSITIVE PATIENTS, CEPHALOSPORIN ANTIBIOTICS SHOULD BE ADMINISTERED CAUTIOUSLY THERE IS CLINICAL AND LABORATORY EVIDENCE OF PARTIAL CROSS-ALLERGENICITY OF THE PENICILLINS AND THE CEPHALOSPORINS, AND THERE ARE INSTANCES IN WHICH PATIENTS HAVE HAD REACTIONS, INCLUDING ANAPHYLAXIS, TO BOTH DRUG CLASSES

Antibiotics, including Ceclor, should be administered cautiously to any patient who has demonstrated some form of allergy, particularly to drugs

Pseudomembranous colitis has been reported with virtually all broad-spectrum antibiotics (including macrolides, semisynthetic penicillins, and cephalosporins); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with the use of antibiotics. Such colitis may range in severity from mild to life-threatening

Treatment with broad-spectrum antibiotics alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate that a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis

Mild cases of pseudomembranous colitis usually respond to drug discontinuance alone. In moderate to severe cases, management should include sigmoidoscopy, appropriate bacteriologic studies, and fluid, electrolyte, and protein supplementation. When the colitis does not improve after the drug has been discontinued, or when it is severe, oral vancomycin is the drug of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should be ruled out

Precautions: *General Precautions* — If an allergic reaction to Ceclor* (cefaclor, Lilly) occurs, the drug should be discontinued, and, if necessary, the patient should be treated with appropriate agents, e.g., pressor amines, antihistamines, or corticosteroids

Prolonged use of Ceclor may result in the overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken

Positive direct Coombs' tests have been reported during treatment with the cephalosporin antibiotics. In hematologic studies or in transfusion cross-matching procedures when antiglobulin tests are performed on the minor side or in Coombs' testing of newborns whose mothers have received cephalosporin antibiotics before parturition, it should be recognized that a positive Coombs' test may be due to the drug

Ceclor should be administered with caution in the presence of markedly impaired renal function. Under such conditions, careful clinical observation and laboratory studies should be made because safe dosage may be lower than that usually recommended

As a result of administration of Ceclor, a false-positive reaction for glucose in the urine may occur. This has been observed with Benedict's and Fehling's solutions and also with Clinitest* tablets but not with Tes-Tape* (Glucose Enzymatic Test Strip, USP, Lilly).

Broad-spectrum antibiotics should be prescribed with caution in individuals with a history of gastrointestinal disease, particularly colitis

Usage in Pregnancy — *Pregnancy Category B* — Reproduction studies have been performed in mice and rats at doses up to 12 times the human dose and in ferrets given three times the maximum human dose and have revealed no evidence of impaired fertility or harm to the fetus due to Ceclor* (cefaclor, Lilly). There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers — Small amounts of Ceclor have been detected in mother's milk following administration of single 500-mg doses. Average levels were 0.18, 0.20, 0.21, and 0.16 mcg/ml at two, three, four, and five hours respectively. Trace amounts were detected at one hour. The effect on nursing infants is not known. Caution should be exercised when Ceclor is administered to a nursing woman.

Usage in Children — Safety and effectiveness of this product for use in infants less than one month of age have not been established.

Adverse Reactions: Adverse effects considered related to therapy with Ceclor are uncommon and are listed below.

Gastrointestinal symptoms occur in about 2.5 percent of patients and include diarrhea (1 in 70).

Symptoms of pseudomembranous colitis may appear either during or after antibiotic treatment. Nausea and vomiting have been reported rarely.

Hypersensitivity reactions have been reported in about 1.5 percent of patients and include morbilliform eruptions (1 in 100). Pruritus, urticaria, and positive Coombs' tests each occur in less than 1 in 200 patients. Cases of serum-sickness-like reactions (erythema multiforme or the above skin manifestations accompanied by arthritis/arthralgia and, frequently, fever) have been reported. These reactions are apparently due to hypersensitivity and have usually occurred during or following a second course of therapy with Ceclor. Such reactions have been reported more frequently in children than in adults. Signs and symptoms usually occur a few days after initiation of therapy and subside within a few days after cessation of therapy. No serious sequelae have been reported. Antihistamines and corticosteroids appear to enhance resolution of the syndrome.

Cases of anaphylaxis have been reported, half of which have occurred in patients with a history of penicillin allergy.

Other effects considered related to therapy included eosinophilia (1 in 50 patients) and genital pruritus or vaginitis (less than 1 in 100 patients).

Causal Relationship Uncertain — Transitory abnormalities in clinical laboratory test results have been reported. Although they were of uncertain etiology, they are listed below to serve as alerting information for the physician.

Hepatic — Slight elevations in SGOT, SGPT, or alkaline phosphatase values (1 in 40).

Hematopoietic — Transient fluctuations in leukocyte count, predominantly lymphocytosis occurring in infants and young children (1 in 40).

Renal — Slight elevations in BUN or serum creatinine (less than 1 in 500) or abnormal urinalysis (less than 1 in 200).

[D617B2R]

Note: Ceclor* (cefaclor, Lilly) is contraindicated in patients with known allergy to the cephalosporins and should be given cautiously to penicillin-allergic patients.

Penicillin is the usual drug of choice in the treatment and prevention of streptococcal infections, including the prophylaxis of rheumatic fever. See prescribing information.

INFORMATION FOR AUTHORS

Submitting Manuscripts

Manuscripts for consideration should be sent to the editor, Malcolm S. M. Watts, MD, 44 Gough Street, San Francisco, California 94103. The transmittal letter should designate one person as correspondent and include complete address, with ZIP code and telephone number.

In view of *The Copyright Revision Act of 1976,* transmittal letters should contain the following language: "In consideration for reviewing and editing my submission, the author(s) undersigned hereby transfers, assigns or otherwise conveys all copyright ownership to THE WESTERN JOURNAL OF MEDICINE in the event that such work is published by the journal." This statement should be signed by *all* the authors.

Authors are urged to seek clarity and succinctness in all manuscripts regardless of subject matter or format and to give close attention to syntax, grammar and spelling.

Clinical Investigation Section

Articles that authors wish to have considered for the Clinical Investigation section should be so designated in the transmittal letter. The type of articles appropriate for this section are those that describe experimental work in humans that extensively and prospectively examines scientific hypotheses relating to disease. An article describing a single case report will not normally be considered appropriate for this section.

Preparing Manuscripts

The original manuscript and *two* copies should be submitted on heavy bond paper (8½ by 11 inches, *not* erasable), typed *double-spaced throughout* (including legends, tables and references) on one side of the paper, with 1½-inch margins. Ordinarily, articles should not exceed 3,000 words (less than 15 text pages, typed double-spaced). Under exceptional circumstances only will articles longer than 4,000 words be published. Pages should be numbered consecutively, beginning with the title page.

Style

Abbreviations. Use of abbreviations should be minimized. If they are necessary, abbreviations should be spelled out at first mention, with the abbreviation itself immediately following in parentheses.

Weights and measures. All measurements should be given in metric units. English equivalents should be given parenthetically if the measurements were originally done in English units.

Temperatures. Temperature readings should be given first in Celsius, followed by the Fahrenheit equivalent in parentheses.

Drug names. If the trade name of a drug is used, the generic name should be given first, followed by the trade name in parentheses. Trade names are capitalized, generic names are not.

Title Page

Titles are best when brief and concise. The title page should include the full name of the author(s), with degrees, academic or professional titles, complete addresses and any institutional or other affiliations. The complete name and address of the person who will handle reprint requests also should appear on this page.

Abstract

The abstract (approximately 150 words) should be a short summary, saying in brief what is said at length in the body of the article—rather than such and such "is discussed," "is presented" or "was investigated."

Tables and Figures

Tables

Each table should be typed on a separate sheet of paper, be numbered consecutively in Arabic numerals, have a brief descriptive title and have its position indicated in the text.

Illustrations (Figures)

Three sets of clear, unmounted black and white glossy prints of figures should be submitted (preferably 5 by 7 inches, but no larger than 8½ by 11 inches). For line drawings, original artwork or glossy prints are acceptable. Illustrations should be numbered consecutively in Arabic numerals and their position indicated in the text. Figure number, first author's name and top of the photo should be shown on the reverse side of each illustration. Recognizable photographs of patients are to be masked and written permission for publication obtained from the patients.

Legends

All legends for figures should be typed together on a separate sheet of paper. Magnification and stain for photomicrographs should be indicated in parentheses.

Permission for Reproduction

If an illustration or table has been used previously in another publication, written permission for its use must be obtained from the publisher, and should accompany the manuscript. The source should be acknowledged in the legend if it can be done briefly by citation of a reference number. Otherwise, acknowledgment is made at the end of the figure legend or at the bottom of the table.

References

References should be limited to those cited in the text. They must be typed double-spaced and numbered consecutively as they appear in the manuscript. (See examples below for style.) Abbreviations of journal titles should conform to those used in *Index Medicus.*

Journal Articles

Note handling of multiple authorship. If more than three authors are listed as contributors, use "et al" to designate those names after the first three. Also note capitalization, punctuation, mention of inclusive page numbers and year of publication. Separate the subtitle from the title by either a dash or a colon. Use colon *only* if it appears in the original citation.

1. Jones JS, Anderson HW, Johnson DW, et al: The athletic heart revisited—Sudden death of a 28-year-old athlete. JAMA 1978; 292:444-456

2. Graybill JR, Alford RH, Smith RG, et al: Cell-mediated immunity in cryptococcosis: A brief review. Cell Immunol 1978; 7:76-79

Books

Note handling of "edition," "editor(s)," and "volume," as well as appropriate sequence of reference information and capitalization of chapters and titles.

3. Berne EJ, Smith TL: Role playing in therapy, chap 2, Principles of Group Therapy. New York, Oxford University Press, 1966, pp 35-51 *(author of chapter same as author of book)*

4. Munsung JM: The role of drugs, chap 2, *In* Brest AN, Mayer JH (Eds): Hypertension—Vol 2, Therapy, 2nd Ed. Springfield, Ill, Charles C Thomas, 1961, pp 456-479 *(author of chapter different from authors of book)*

Pamphlets, Monographs or Books With No Given Author

5. AMA Department of Drugs: AMA Drug Evaluation, 3rd Ed. Littleton, Mass, Publishing Sciences Group, 1977 *(corporate author)*

6. Compilation of Standard Definitions, 3rd Ed. Philadelphia, American Society for Testing and Materials, 1976 *(no given author; give name and place of publisher)*

Articles in Press or Accepted for Publication

Any article accepted for publication should include the name of the journal (appropriately abbreviated) in which it will appear, and the phrase "in press" or "accepted for publication" in place of the date of publication.

Personal Communications and Unpublished Data

This information should *not* be included in the reference list but should be given in parentheses in the body of the text. Date of communication, whether it was personal or written, and the person's name, highest academic degree and professional affiliation should be provided.

Acknowledgments

It is the policy of the *WJM* not to print acknowledgments, the feeling being that if a person has contributed enough to a paper to be mentioned, he or she should be included among the authors, or the contribution should be mentioned in the body of the paper or in a footnote.

Correspondence

Brief manuscripts commenting on articles that have appeared in the journal, containing information of interest to physicians or discussing issues of the day will be considered for publication. Very short reports of cases, clinical experience, clinical studies, adverse effects and the like also will be considered. Items for the Correspondence section should not exceed 600 words and should have no more than five bibliographic references and one figure or table.

Author Responsibility

Authors are responsible for all statements made in articles. Manuscripts are considered for publication with the explicit understanding that they are original, have not been published previously and are not simultaneously under consideration by any other publication.

All accepted manuscripts are subject to copy editing, and authors are sent edited galleys for approval. No changes will be made after the final, edited version has been approved by the author.

Reprints

If reprints are desired, they must be paid for by the author. A reprint order form with schedule of prices is sent to the author when the article is published. Authors are responsible for handling requests for reprints of their articles.

When the pain and inflammation of arthritis flare up...

- FELDENE is an excellent choice for osteoarthritis and rheumatoid arthritis. Beginning with the first dose, FELDENE provides effective and long-lasting relief of arthritis pain and stiffness.[1]
- Convenient once-daily dosage provides round-the-clock relief of symptoms[2]—encouraging compliance and enhancing productivity at home and on the job.[3]

Start one-a-day

Feldene® (PIROXICAM) 20 mg capsules

For full anti-arthritic action

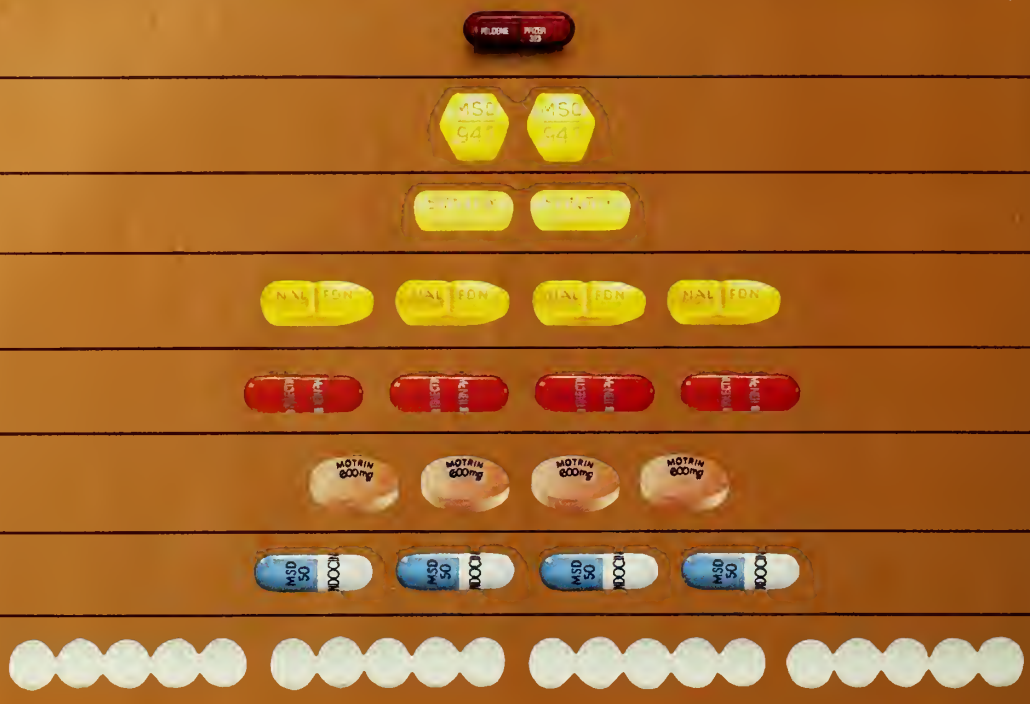
Please see a brief summary of FELDENE (piroxicam) prescribing information on the following page.

Start one-a-day

Feldene® (PIROXICAM) 20 mg capsules

For full anti-arthritic action

Prescribe one 20mg capsule daily for convenience and compliance



Source: PDR, 1985; Manufacturers' Prescribing Information.

Indicates maximum dosage for osteoarthritis and rheumatoid arthritis for the antiarthritic agents included. Consult manufacturers' prescribing information.

Brief Summary

FELDENE® (piroxicam) Capsules

CONTRAINDICATIONS: FELDENE (piroxicam) should not be used in patients who have previously exhibited hypersensitivity to it, or in individuals with the syndrome comprised of bronchospasm, nasal polyps and angioedema precipitated by aspirin or other nonsteroidal anti-inflammatory drugs.

WARNINGS: Peptic ulceration, perforation and G.I. bleeding—sometimes severe, and, in some instances fatal—have been reported with patients receiving FELDENE. If FELDENE must be given to patients with a history of upper gastrointestinal tract disease, the patient should be under close supervision (see ADVERSE REACTIONS).

PRECAUTIONS: As with other anti-inflammatory agents, long-term administration to animals results in renal papillary necrosis and related pathology in rats, mice and dogs.

Acute renal failure and hyperkalemia as well as reversible elevations of BUN and serum creatinine have been reported with FELDENE. In addition to reversible changes in renal function, interstitial nephritis, glomerulitis, papillary necrosis and the nephrotic syndrome have been reported with FELDENE.

Although other nonsteroidal anti-inflammatory drugs do not have the same direct effect on platelets that aspirin does, all drugs inhibiting prostaglandin biosynthesis do interfere with platelet function to some degree.

Because of reports of adverse eye findings with nonsteroidal anti-inflammatory agents, it is recommended that patients who develop visual complaints during treatment with FELDENE have ophthalmic evaluation.

As with other nonsteroidal anti-inflammatory drugs, borderline elevations of one or more liver tests may occur in up to 15% of patients. A patient with symptoms and/or signs suggesting liver dysfunction, or in whom abnormal liver tests have occurred, should be evaluated for evidence of the development of more severe hepatic reaction while on therapy with FELDENE.

Severe hepatic reactions, including jaundice and cases of fatal hepatitis have been reported with FELDENE. Although such reactions are rare, if abnormal liver tests persist or worsen, if clinical signs and symptoms consistent with liver disease develop, or if systemic manifestations occur (e.g., eosinophilia, rash, etc.), FELDENE should be discontinued. (See also ADVERSE REACTIONS.)

Although at the recommended dose of 20 mg/day of FELDENE increased fecal blood loss due to gastrointestinal irritation did not occur, in about 4% of the patients treated with FELDENE alone or concomitantly with aspirin, reductions in hemoglobin and hematocrit values were observed.

Peripheral edema has been observed in approximately 2% of the patients treated with FELDENE. Therefore, FELDENE should be used with caution in patients with heart failure, hypertension or other conditions predisposing to fluid retention.

A combination of dermatological and/or allergic signs and symptoms suggestive of serum sickness have occasionally occurred in conjunction with the use of FELDENE. These include arthralgias, pruritus, fever, fatigue, and rash including vesiculo bullous reactions and exfoliative dermatitis.

DRUG INTERACTIONS: Interactions with coumarin-type anticoagulants have been reported with FELDENE since marketing. Therefore, physicians should closely monitor patients for a change in dosage requirements when administering FELDENE to patients on coumarin-type anticoagulants and other highly protein-bound drugs.

Plasma levels of piroxicam are depressed to approximately 80% of their normal values when FELDENE is administered in conjunction with aspirin (3900 mg/day), but concomitant administration of antacids has no effect on piroxicam plasma levels.

Nonsteroidal anti-inflammatory agents, including FELDENE, have been reported to increase steady state plasma lithium levels. It is recommended that plasma lithium levels be monitored when initiating, adjusting and discontinuing FELDENE.

Carcinogenesis, Chronic Animal Toxicity and Impairment of Fertility: Subacute and chronic toxicity studies have been carried out in rats, mice, dogs, and monkeys.

The pathology most often seen was that characteristically associated with the animal toxicology of anti-inflammatory agents: renal papillary necrosis (see PRECAUTIONS) and gastrointestinal lesions.

In classical studies in laboratory animals, piroxicam did not show any teratogenic potential.

Reproductive studies revealed no impairment of fertility in animals.

Pregnancy and Nursing Mothers: Like other drugs which inhibit the synthesis and release of prostaglandins, piroxicam administration continued late into pregnancy increased the incidence of dystocia and delayed parturition in animals. Gastrointestinal tract toxicity was increased in pregnant females in the last trimester of pregnancy compared to non-pregnant females or females in earlier trimesters of pregnancy.

FELDENE is not recommended for use in nursing mothers or in pregnant women because of the animal findings and since safety for such use has not been established in humans.

Use in Children: Dosage recommendations and indications for use in children have not been established.

ADVERSE REACTIONS: Gastrointestinal symptoms are the most prominent side effects, occurring in approximately 20% of the patients, which in most instances did not interfere with the course of therapy. Of the patients experiencing gastrointestinal side effects, approximately 5% discontinued therapy with an overall incidence of peptic ulceration of about 1%.

Adverse reactions are listed below by body system for all patients in clinical trials with FELDENE at doses of 20 mg/day.

Incidence Greater Than 1%: The following adverse reactions occurred more frequently than 1 in 100.

Gastrointestinal: stomatitis, anorexia, epigastric distress*, nausea*, constipation, abdominal discomfort, flatulence, diarrhea, abdominal pain, indigestion

Hematological: decreases in hemoglobin* and hematocrit* (see PRECAUTIONS), anemia, leucopenia, eosinophilia

Dermatologic: pruritus, rash

Central Nervous System: dizziness, somnolence, vertigo

Urogenital: BUN and creatinine elevations (see PRECAUTIONS)

Body as a Whole: headache, malaise

Special Senses: tinnitus

Cardiovascular/Respiratory: edema (see PRECAUTIONS)

*Reactions occurring in 3% to 9% of patients treated with FELDENE (piroxicam).

Reactions occurring in 1% to 3% of patients are unmarked.

Incidence Less Than 1% (Causal Relationship Probable): The following adverse reactions occurred less frequently than 1 in 100. The probability exists that there is a causal relationship between FELDENE and these reactions.

Gastrointestinal: liver function abnormalities, jaundice, hepatitis (see PRECAUTIONS), vomiting, hematemesis, melena, gastrointestinal bleeding, perforation and ulceration (see WARNINGS), dry mouth

Hematological: thrombocytopenia, petechial rash, ecchymosis, bone marrow depression including aplastic anemia, epistaxis

Dermatologic: sweating, erythema, bruising, desquamation, exfoliative dermatitis, erythema multiforme, toxic epidermal necrolysis, Stevens-Johnson syndrome, vesiculo bullous reactions, photoallergic skin reactions

Central Nervous System: depression, insomnia, nervousness

Urogenital: hematuria, proteinuria, interstitial nephritis, renal failure, hyperkalemia, glomerulitis, papillary necrosis, nephrotic syndrome (see PRECAUTIONS)

Body as a Whole: pain (colic), fever, flu-like syndrome (see PRECAUTIONS)

Special Senses: swollen eyes, blurred vision, eye irritations

Cardiovascular/Respiratory: hypertension, worsening of congestive heart failure (see PRECAUTIONS), exacerbation of angina

Metabolic: hypoglycemia, hyperglycemia, weight increase, weight decrease

Hypersensitivity: anaphylaxis, bronchospasm, urticaria/angioedema, vasculitis, "serum sickness" (see PRECAUTIONS)

Incidence Less Than 1% (Causal Relationship Unknown): Other adverse reactions were reported with a frequency of less than 1 in 100, but a causal relationship between FELDENE and the reaction could not be determined.

Gastrointestinal: pancreatitis

Dermatologic: onycholysis, loss of hair

Central Nervous System: akathisia, hallucinations, mood alterations, dream abnormalities, mental confusion, paresthesias

Urogenital System: dysuria

Body as a Whole: weakness

Cardiovascular/Respiratory: palpitations, dyspnea

Hypersensitivity: positive ANA

OVERDOSAGE: In the event treatment for overdosage is required, the long plasma half-life of piroxicam should be considered. The absence of experience with acute overdosage precludes characterization of sequelae and recommendations of specific antidotal efficacy at this time. It is reasonable to assume that the standard measures of gastric evacuation and general supportive therapy would apply. In addition to supportive measures, the use of activated charcoal may effectively reduce the absorption and reabsorption of piroxicam. Experiments in dogs have demonstrated that the use of multiple-dose treatments with activated charcoal could reduce the half-life of piroxicam elimination from 27 hours (without charcoal) to 11 hours and reduce the systemic bioavailability of piroxicam by as much as 37% when activated charcoal is given as late as 6 hours after administration of piroxicam.

ADMINISTRATION AND DOSAGE: Rheumatoid Arthritis, Osteoarthritis. It is recommended that FELDENE therapy be initiated and maintained at a single daily dose of 20 mg. If desired, the daily dose may be divided.

Dosage recommendations and indications for use in children have not been established.

More detailed professional information available on request.

SORBITRATE®
(ISOSORBIDE DINITRATE)

Please consult full prescribing information before use. A summary follows:

INDICATIONS AND USAGE: SORBITRATE (isosorbide dinitrate) is indicated for the treatment and prevention of angina pectoris. All dosage forms of isosorbide dinitrate may be used prophylactically to decrease frequency and severity of anginal attacks and can be expected to decrease the need for sublingual nitroglycerin.

The sublingual and chewable forms of the drug are indicated for acute prophylaxis of angina pectoris when taken a few minutes before situations likely to provoke anginal attacks. Because of a slower onset of effect, the oral forms of isosorbide dinitrate are not indicated for acute prophylaxis.

CONTRAINDICATIONS: SORBITRATE is contraindicated in patients who have shown purported hypersensitivity or idiosyncrasy to it or other nitrates or nitrites. Epinephrine and related compounds are ineffective in reversing the severe hypotensive events associated with overdose and are contraindicated in this situation.

WARNINGS: The benefits of SORBITRATE during the early days of an acute myocardial infarction have not been established. If one elects to use organic nitrates in early infarction, hemodynamic monitoring and frequent clinical assessment should be used because of the potential deleterious effects of hypotension.

PRECAUTIONS: General: Severe hypotensive response, particularly with upright posture, may occur with even small doses of SORBITRATE. The drug should therefore be used with caution in subjects who may have blood volume depletion from diuretic therapy or in subjects who have low systolic blood pressure (eg, below 90 mmHg). Paradoxical bradycardia and increased angina pectoris may accompany nitrate-induced hypotension. Nitrate therapy may aggravate the angina caused by hypertrophic cardiomyopathy.

Marked symptomatic, orthostatic hypotension has been reported when calcium channel blockers and organic nitrates were used in combination. Dose adjustment of either class of agents may be necessary.

Tolerance to this drug and cross-tolerance to other nitrates and nitrites may occur. Tolerance to the vascular and antianginal effects of isosorbide dinitrate or nitroglycerin has been demonstrated in clinical trials, experience through occupational exposure, and in isolated tissue experiments in the laboratory. The importance of tolerance to the appropriate use of isosorbide dinitrate in the management of patients with angina pectoris has not been determined. However, one clinical trial using treadmill exercise tolerance (as an end point) found an 8-hour duration of action of oral isosorbide dinitrate following the first dose (after a 2-week placebo washout) and only a 2-hour duration of effect of the same dose after 1 week of repetitive dosing at conventional dosing intervals. On the other hand, several trials have been able to differentiate isosorbide dinitrate from placebo after 4 weeks of therapy and, in open trials, an effect seems detectable for as long as several months.

Tolerance clearly occurs in industrial workers continuously exposed to nitroglycerin. Moreover, physical dependence also occurs since chest pain, acute myocardial infarction, and even sudden death have occurred during temporary withdrawal of nitroglycerin from the workers. In clinical trials in angina patients, there are reports of anginal attacks being more easily provoked and of rebound in the hemodynamic effects soon after nitrate withdrawal. The relative importance of these observations to the routine, clinical use of isosorbide dinitrate is not known. However, it seems prudent to gradually withdraw patients from isosorbide dinitrate when the therapy is being terminated, rather than stopping the drug abruptly.

Information for Patients: Headache may occur during initial therapy with SORBITRATE. Headache is usually relieved by the use of standard headache remedies or by lowering the dose and tends to disappear after the first week or two of use.

Drug Interactions: Alcohol may enhance any marked sensitivity to the hypotensive effect of nitrates.

Isosorbide dinitrate acts directly on vascular smooth muscle, therefore, any other agent that depends on vascular smooth muscle as the final common path can be expected to have decreased or increased effect depending on the agent.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No long-term studies in animals have been performed to evaluate the carcinogenic potential of this drug. A modified two-litter reproduction study in rats fed isosorbide dinitrate at 25 or 100 mg/kg/day did not reveal any effects on fertility or gestation or any remarkable gross pathology in any parent or offspring fed isosorbide dinitrate as compared with rats fed a basal-controlled diet.

Pregnancy Category C: Isosorbide dinitrate has been shown to cause a dose-related increase in embryotoxicity (increase in mummified pups) in rabbits at oral doses 35 and 150 times the maximum recommended human daily dose. There are no adequate and well-controlled studies in pregnant women. SORBITRATE should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when SORBITRATE is administered to a nursing woman.

Pediatric Use: The safety and effectiveness of SORBITRATE in children has not been established.

ADVERSE REACTIONS: Adverse reactions, particularly headache and hypotension, are dose-related. In clinical trials at various doses, the following have been observed:

Headache is the most common (reported incidence varies widely, apparently being dose-related, with an average occurrence of about 25%) adverse reaction and may be severe and persistent. Cutaneous vasodilation with flushing may occur. Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop (the incidence of reported symptomatic hypotension ranges from 2% to 36%). An occasional individual will exhibit marked sensitivity to the hypotensive effects of nitrates and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration, and collapse) may occur even with the usual therapeutic dose. Drug rash and/or exfoliative dermatitis may occasionally occur. Nausea and vomiting appear to be uncommon. Case reports of clinically significant methemoglobinemia are rare at conventional doses of organic nitrates. The formation of methemoglobin is dose-related and, in the case of genetic abnormalities of hemoglobin that favor methemoglobin formation, even conventional doses of organic nitrate could produce harmful concentrations of methemoglobin.

DOSAGE AND ADMINISTRATION: For the treatment of angina pectoris, the usual starting dose for sublingual SORBITRATE is 2.5 to 5 mg; for chewable tablets, 5 mg, for oral (swallowed) tablets, 5 to 20 mg, and for controlled-release forms, 40 mg.

SORBITRATE should be titrated upward until angina is relieved or side effects limit the dose. In ambulatory patients, the magnitude of the incremental dose increase should be guided by measurements of standing blood pressure.

The initial dosage of sublingual or chewable SORBITRATE for prophylactic therapy in angina pectoris patients is generally 5 or 10 mg every 2 to 3 hours. Adequate controlled clinical studies demonstrating the effectiveness of chronic maintenance therapy with these dosage forms have not been reported.

SORBITRATE in oral doses of 10 to 40 mg given every 6 hours or in oral controlled-release doses of 40 to 80 mg given every 8 to 12 hours is generally recommended. The extent to which development of tolerance should modify the dosage program has not been defined. *The oral controlled-release forms of isosorbide dinitrate should not be chewed.*

DOSAGE FORMS AVAILABLE: Sublingual Tablets (2.5, 5, 10 mg); Chewable Tablets (5, 10 mg); Oral Tablets (5, 10, 20, 30, 40 mg); Sustained Action Tablets (40 mg)

Precautionary guidelines

CAPOTEN® (captopril tablets) has been associated with the development of neutropenia/agranulocytosis (0.3% of 4,000 patients) or proteinuria (1.2% of 4,000 patients).† These serious side effects are more likely to occur in patients with predisposing conditions, such as renal impairment or autoimmune disease, or in patients receiving therapy known to suppress the immune response. The following precautionary guidelines are recommended for all patients receiving CAPOTEN:

☐ Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.

☐ Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.

☐ Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.

☐ The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.

†Please see brief summary for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

CAPOTEN* TABLETS
Captopril Tablets

INDICATIONS: Hypertension – Because serious adverse effects have been reported (see WARNINGS), CAPOTEN is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects.

Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.

WARNINGS: Proteinuria – Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about one-fourth of these cases. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients.

Membranous glomerulopathy was found in nearly all of the proteinuric patients on captopril who were biopsied and may be drug related. Most cases of proteinuria occurred by the eighth month of therapy. Patients should have urinary protein estimates (dip-stick on first morning urine, or quantitative 24-hour urine – the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approximate monthly intervals for the first nine months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis – Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about two weeks (other than two patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the first 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller. In these patients white blood cell counts should be performed every 2 weeks for the first 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.

Hypotension – Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in mean blood pressure >20% were recorded in about half of the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first two weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.

PRECAUTIONS: General: *Impaired Renal Function,* Hypertension – Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure – About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* – A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis, due to decreased afterload reduction.

Surgery/Anesthesia – If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.

Drug Interactions: *Hypotension: Patients on Diuretic Therapy* – Precipitous reduction of blood pressure may occasionally occur within the first 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose in hypertensive patients.

Agents Having Vasodilator Activity – In heart failure patients vasodilators should be administered with caution.

Agents Causing Renin Release – Captopril's effect will be augmented by antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity – The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium – Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Usage in Pregnancy: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus.

(continued on next page)

© 1985 E R Squibb & Sons, Inc., Princeton, NJ 08540 525-568 Issued June 1985

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving approximately 4000 patients.

Renal—One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic—Neutropenia/agranulocytosis occurred in about 0.3% of captopril-treated patients (see WARNINGS). Two of these patients developed sepsis and died.

Dermatologic—Rash (usually maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the first 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients—reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular—Hypotension in about 2 of 100 patients. See WARNINGS (Hypotension) and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia—About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with secondary cholestasis, have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern in correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN (captopril) should be taken one hour before meals. In hypertension, CAPOTEN may be dosed bid or tid. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.
Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 12.5, 25, 50, and 100 mg in bottles of 100 (25 mg also available in bottles of 1000), and in UNIMATIC® single dose packs of 100 tablets. (J3-658B)

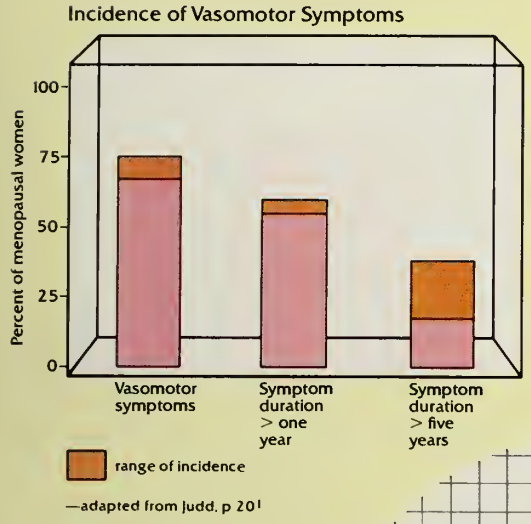
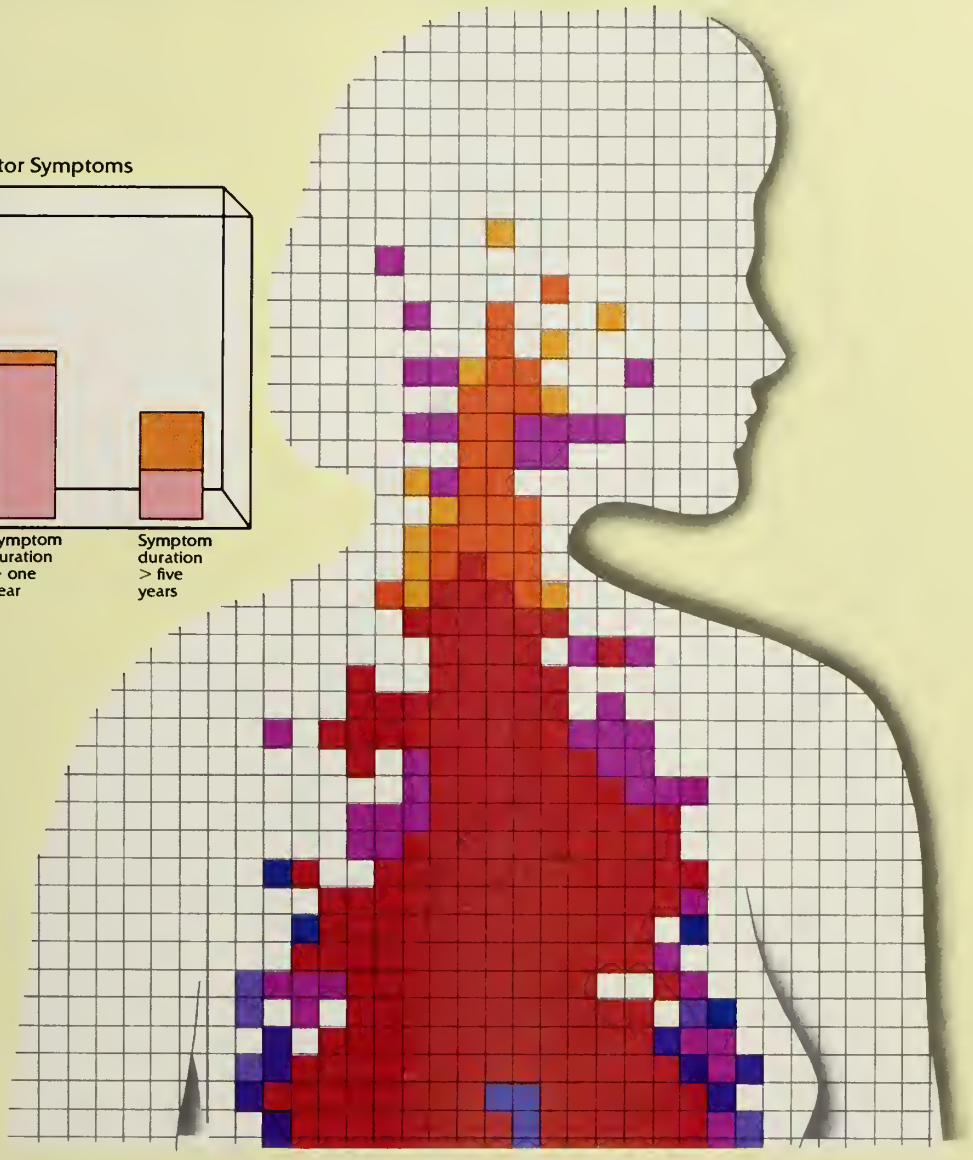
VASOMOTOR SYMPTOMS THAT DEMAND INTERVENTION



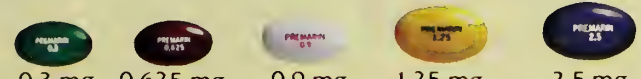


PREMARIN RELIEVES MODERATE TO SEVERE VASOMOTOR SYMPTOMS

Vasomotor symptoms are the most common manifestation of the menopause, affecting up to 75% of menopausal women. Of these, 80% may suffer for more than a year and up to 50% for more than five years.[1] These symptoms can disrupt a woman's life by chronically interrupting sleep, resulting in anxiety and irritability.

In a study of postmenopausal women suffering severe episodes of cutaneous flushing, symptoms improved markedly after administration of estrogen[2]—the treatment of choice for moderate to severe vasomotor symptoms.[3] The estrogen of choice is PREMARIN, the most widely prescribed estrogen for over 40 years. PREMARIN (Conjugated Estrogens Tablets, U.S.P.) relieves moderate to severe vasomotor symptoms of the natural menopause, as well as the acute and often severe symptoms of surgical menopause.

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)

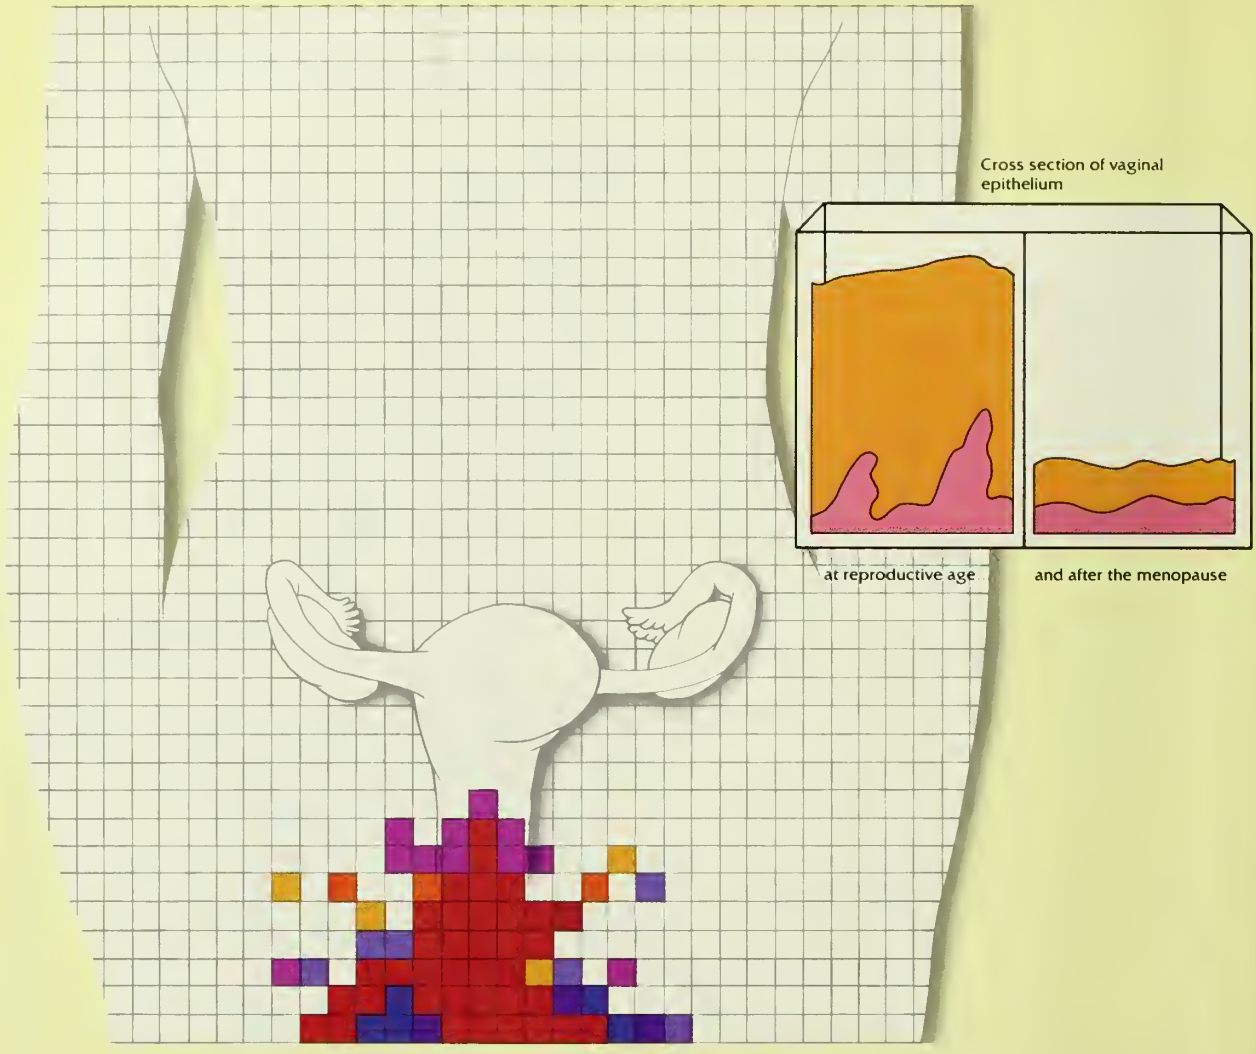


0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg

The appearance of these tablets is a trademark of Ayerst Laboratories.

Please see last page for brief summary of full prescribing information.

VAGINAL ATROPHY THAT INTERFERES WITH SEXUALITY



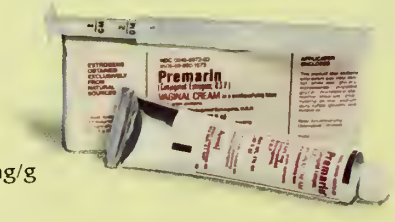
PREMARIN RESTORES THE VAGINAL ENVIRONMENT

In the postmenopausal woman, decreasing levels of estrogen can have devastating effects on a woman's sexual functioning. The pH of vaginal secretions rises, promoting the growth of contaminating organisms. The vaginal epithelium dries and thins, becoming susceptible to irritation, injury, and infection. Sexual relations may be difficult or impossible.

PREMARIN (Conjugated Estrogens, U.S.P.) Vaginal Cream focuses therapy at the site of the problem. Vaginal dryness is relieved, pH reverts to its normal acidity, and the epithelium thickens and becomes more resistant to injury and infection. With the vaginal environment returned to its premenopausal state, sexual function may improve.

PREMARIN®

(CONJUGATED ESTROGENS, U.S.P.) Vaginal Cream

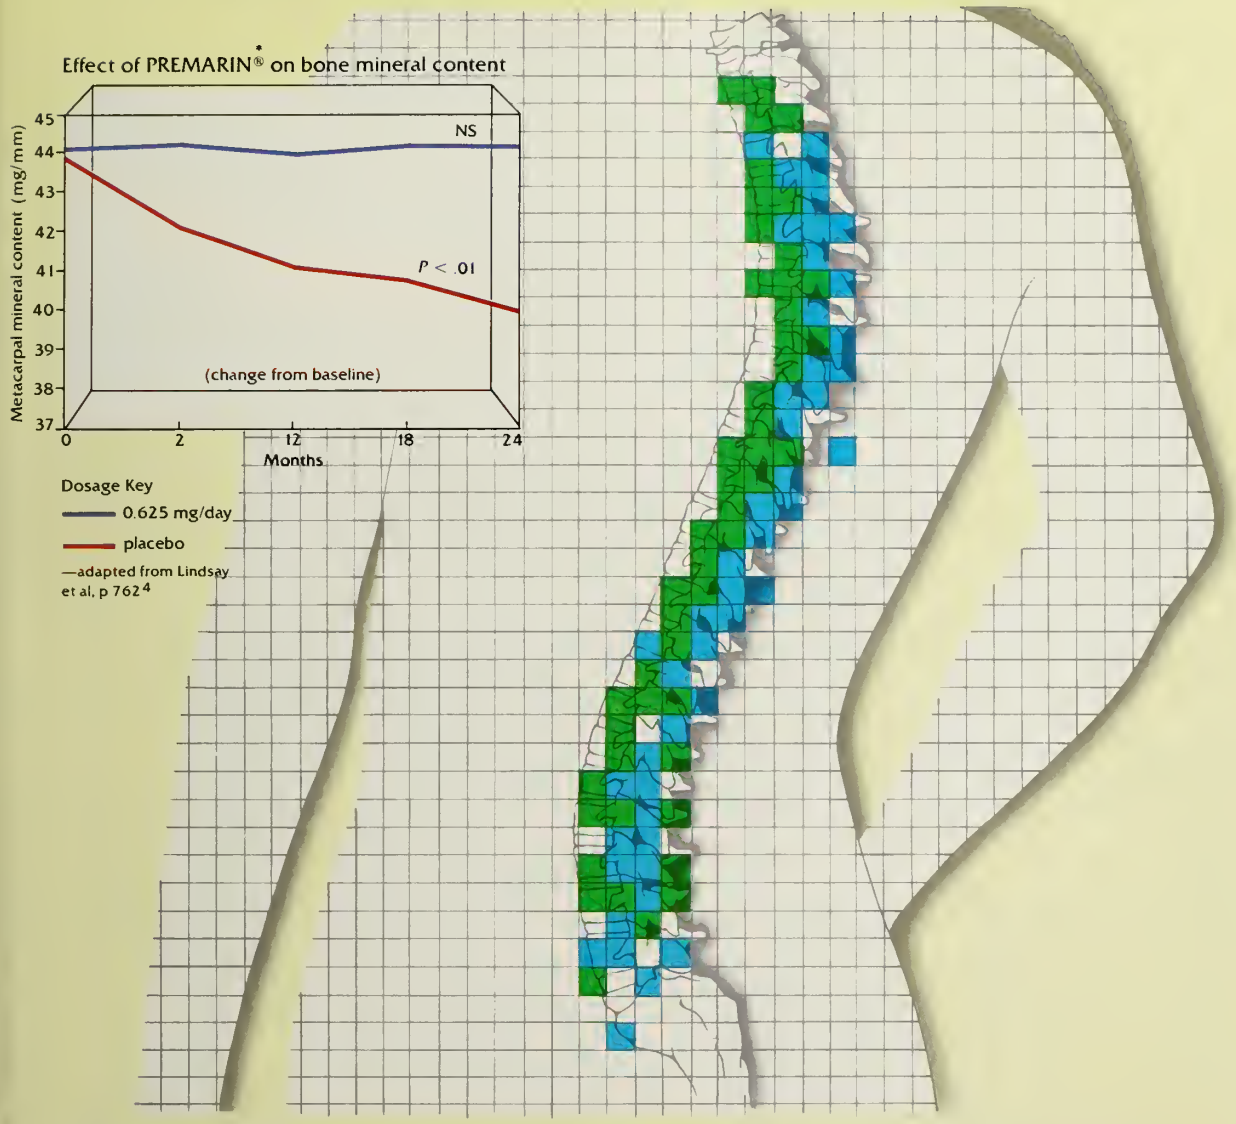


0.625 mg/g

© 1985 Ayerst Laboratories

Please see last page for brief summary of full prescribing information.

POSTMENOPAUSAL BONE LOSS THAT INCAPACITATES

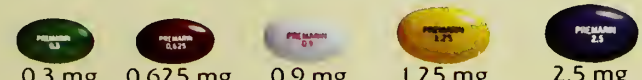


PREMARIN MAY HALT THE DISABLING COURSE OF OSTEOPOROSIS*

Osteoporosis has an enormous epidemiological impact: it affects 10 million American women, and 26% of all women over age 60.[5] The disease begins silently and progresses inexorably for 15 to 20 years, until disabling complications occur.[6]

To minimize osteoporotic damage, the condition must be detected early and treated promptly. For many patients, PREMARIN is optimal therapy for osteoporosis, as part of a comprehensive program that includes exercise, good nutrition, and calcium supplements. In a controlled study of postmenopausal and oophorectomized women, PREMARIN (Conjugated Estrogens Tablets, U.S.P.) doses of 0.625 mg/day prevented loss of metacarpal mineral content (see graph above).[4]

PREMARIN®
(CONJUGATED ESTROGENS TABLETS, U.S.P.)



0.3 mg 0.625 mg 0.9 mg 1.25 mg 2.5 mg

The appearance of these tablets is a trademark of Ayerst Laboratories.

*Conjugated Estrogens Tablets have been evaluated as probably effective for estrogen-deficiency-induced osteoporosis.

Please see last page for brief summary of full prescribing information.

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION AND PATIENT INFORMATION, SEE PACKAGE CIRCULAR)*

PREMARIN® Brand of Conjugated Estrogens Tablets, U.S.P.
PREMARIN® Brand of Conjugated Estrogens, U.S.P. Vaginal Cream in a nonliquefying base

1. ESTROGENS HAVE BEEN REPORTED TO INCREASE THE RISK OF ENDOMETRIAL CARCINOMA

Three independent case control studies have reported an increased risk of endometrial cancer in postmenopausal women exposed to exogenous estrogens for more than one year. This risk was independent of the other known risk factors for endometrial cancer. These studies are further supported by the finding that incidence rates of endometrial cancer have increased sharply since 1969 in eight different areas of the United States with population-based cancer reporting systems, an increase which may be related to the rapidly expanding use of estrogens during the last decade. The three case control studies reported that the risk of endometrial cancer in estrogen users was about 4.5 to 13.9 times greater than in nonusers. The risk appears to depend on both duration of treatment and on estrogen dose. In view of these findings, when estrogens are used for the treatment of menopausal symptoms, the lowest dose that will control symptoms should be utilized and medication should be discontinued as soon as possible. When prolonged treatment is medically indicated, the patient should be reassessed on at least a semiannual basis to determine the need for continued therapy. Although the evidence must be considered preliminary, one study suggests that cyclic administration of low doses of estrogen may carry less risk than continuous administration; it therefore appears prudent to utilize such a regimen. Close clinical surveillance of all women taking estrogens is important. In all cases of undiagnosed persistent or recurring abnormal vaginal bleeding, adequate diagnostic measures should be undertaken to rule out malignancy. There is no evidence at present that "natural" estrogens are more or less hazardous than "synthetic" estrogens at equiestrogenic doses.

2. ESTROGENS SHOULD NOT BE USED DURING PREGNANCY.

The use of female sex hormones, both estrogens and progestogens, during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a non-steroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated as not greater than 4 per 1000 exposures. Furthermore, a high percentage of such exposed women (from 30 to 90 percent) have been found to have vaginal adenosis, epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are precursors of malignancy. Although similar data are not available with the use of other estrogens, it cannot be presumed they would not induce similar changes. Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies, including congenital heart defects and limb reduction defects. One case control study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 per 1000. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well controlled studies that progestogens are effective for these uses. If PREMARIN is used during pregnancy, or if the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the advisability of pregnancy continuation.

DESCRIPTION: PREMARIN (Conjugated Estrogens, U.S.P.) contains a mixture of estrogens, obtained exclusively from natural sources, blended to represent the average composition of material derived from pregnant mares' urine. It contains estrone, equilin, and 17α-dihydroequilin, together with smaller amounts of 17α-estradiol, equilenin, and 17α-dihydroequilenin as salts of their sulfate esters.

INDICATIONS: Based on a review of PREMARIN Tablets by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications for use as follows:

Effective: 1. Moderate to severe vasomotor symptoms associated with the menopause. (There is no evidence that estrogens are effective for nervous symptoms or depression without associated vasomotor symptoms, and they should not be used to treat such conditions.)

2. Atrophic vaginitis
3. Kraurosis vulvae
4. Female hypogonadism
5. Female castration
6. Primary ovarian failure
7. Breast cancer (for palliation only) in appropriately selected women and men with metastatic disease.
8. Prostatic carcinoma—palliative therapy of advanced disease.
9. Postpartum breast engorgement—Although estrogens have been widely used for the prevention of postpartum breast engorgement, controlled studies have demonstrated that the incidence of significant painful engorgement in patients not receiving such hormonal therapy is low and usually responsive to appropriate analgesic or other supportive therapy. Consequently, the benefit to be derived from estrogen therapy for this indication must be carefully weighed against the potential increased risk of puerperal thromboembolism associated with the use of large doses of estrogens.

PREMARIN HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

"Probably" effective: For estrogen deficiency-induced osteoporosis, and only when used in conjunction with other important therapeutic measures such as diet, calcium, physiotherapy, and good general health-promoting measures. Final classification of this indication requires further investigation.

INDICATIONS: PREMARIN (Conjugated Estrogens, U.S.P.) Vaginal Cream is indicated in the treatment of atrophic vaginitis and kraurosis vulvae. PREMARIN Vaginal Cream HAS NOT BEEN SHOWN TO BE EFFECTIVE FOR ANY PURPOSE DURING PREGNANCY AND ITS USE MAY CAUSE SEVERE HARM TO THE FETUS (SEE BOXED WARNING).

CONTRAINDICATIONS: Estrogens should not be used in women (or men) with any of the following conditions: 1. Known or suspected cancer of the breast except in appropriately selected patients being treated for metastatic disease. 2. Known or suspected estrogen-dependent neoplasia. 3. Known or suspected pregnancy (See Boxed Warning). 4. Undiagnosed abnormal genital bleeding. 5. Active thrombophlebitis or thromboembolic disorders. 6. A past history of thrombophlebitis, thrombosis, or thromboembolic disorders associated with previous estrogen use (except when used in treatment of breast or prostatic malignancy).

WARNINGS: Long term continuous administration of natural and synthetic estrogens in certain animal species increases the frequency of carcinomas of the breast, cervix, vagina, and liver. There are now reports that estrogens increase the risk of carcinoma of the endometrium in humans. (See Boxed Warning.) At the present time there is no satisfactory evidence that estrogens given to postmenopausal women increase the risk of cancer of the breast, although a recent study has raised this possibility. There is a need for caution in prescribing estrogens for women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease, or abnormal mammograms. A recent study has reported a 2- to 3-fold increase in the risk of surgically confirmed gallbladder disease in women receiving postmenopausal estrogens.

Adverse effects of oral contraceptives may be expected at the larger doses of estrogen used to treat prostatic or breast cancer or postpartum breast engorgement; it has been shown that there is an increased risk of thrombosis in men receiving estrogens for prostatic cancer and women for postpartum breast engorgement. Users of oral contraceptives have an increased risk of diseases, such as thrombophlebitis, pulmonary embolism, stroke, and myocardial infarction. Cases of retinal thrombosis, mesenteric thrombosis, and optic neuritis have been reported in oral contraceptive users. An increased risk of postsurgery thromboembolic complications has also been reported in users of oral contraceptives. If feasible, estrogen should be discontinued at least 4 weeks before surgery of the type associated with an increased risk of thromboembolism, or during periods of prolonged immobilization. Estrogens should not be used in persons with active thrombophlebitis, thromboembolic disorders, or in persons with a history of such disorders in association with estrogen use. They should be used with caution in patients with cerebral vascular or coronary artery disease. Large doses (5 mg conjugated estrogens per day), comparable to those used to treat cancer of the prostate and breast have been shown to increase the risk of nonfatal myocardial infarction, pulmonary embolism and thrombophlebitis. When doses of this size are used, any of the thromboembolic and thrombotic adverse effects should be considered a clear risk.

Benign hepatic adenomas should be considered in estrogen users having abdominal pain and tenderness, abdominal mass, or hypovolemic shock. Hepatocellular carcinoma has been reported in women taking estrogen-containing oral contraceptives. Increased blood pressure may occur with use of estrogens in the menopause and blood pressure should be monitored with estrogen use. A worsening of glucose tolerance has been observed in patients on estrogen-containing oral contraceptives. For this reason, diabetic patients should be carefully observed. Estrogens may lead to severe hypercalcemia in patients with breast cancer and bone metastases.

PRECAUTIONS: Physical examination and a complete medical and family history should be taken prior to the initiation of any estrogen therapy with special reference to blood pressure, breasts, abdomen, and pelvic organs, and should include a Papanicolau smear. As a general rule, estrogen should not be prescribed for longer than one year without another physical examination being performed. Conditions influenced by fluid retention such as asthma, epilepsy, migraine, and cardiac or renal dysfunction, require careful observation. Certain patients may develop manifestations of excessive estrogenic stimulation, such as abnormal or excessive uterine bleeding, mastodynia, etc. Prolonged administration of unopposed estrogen therapy has been reported to increase the risk of endometrial hyperplasia in some patients. Oral contraceptives appear to be associated with an increased incidence of mental depression. Patients with a history of depression should be carefully observed. Preexisting uterine leiomyomata may increase in size during estrogen use. The pathologist should be advised of estrogen therapy when relevant specimens are submitted. If jaundice develops in any patient receiving estrogen, the medication should be discontinued while the cause is investigated. Estrogens should be used with care in patients with impaired liver function, renal insufficiency, metabolic bone diseases associated with hypercalcemia, or in young patients in whom bone growth is not complete.

The following changes may be expected with larger doses of estrogen:

a. Increased sulfobromophthalein retention.
b. Increased prothrombin and factors VII, VIII, IX, and X, decreased antithrombin 3, increased norepinephrine-induced platelet aggregability.
c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by PBI, T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered.
d. Impaired glucose tolerance.
e. Decreased pregnanediol excretion.
f. Reduced response to metyrapone test.
g. Reduced serum folate concentration.
h. Increased serum triglyceride and phospholipid concentration.

As a general principle, the administration of any drug to nursing mothers should be done only when clearly necessary since many drugs are excreted in human milk.

ADVERSE REACTIONS: The following have been reported with estrogenic therapy, including oral contraceptives: breakthrough bleeding, spotting, change in menstrual flow; dysmenorrhea; premenstrual-like syndrome; amenorrhea during and after treatment; increase in size of uterine fibromyomata; vaginal candidiasis, change in cervical erosion and in degree of cervical secretion; cystitis-like syndrome; tenderness, enlargement, secretion (of breasts); nausea, vomiting, abdominal cramps, bloating; cholestatic jaundice; chloasma or melasma which may persist when drug is discontinued, erythema multiforme; erythema nodosum; hemorrhagic eruption; loss of scalp hair, hirsutism; steepening of corneal curvature; intolerance to contact lenses; headache, migraine, dizziness, mental depression, chorea; increase or decrease in weight; reduced carbohydrate tolerance; aggravation of porphyria, edema; changes in libido.

ACUTE OVERDOSAGE: May cause nausea, and withdrawal bleeding may occur in females.

DOSAGE AND ADMINISTRATION:

PREMARIN® Brand of Conjugated Estrogens Tablets, U.S.P.

1. *Given cyclically for short-term use only:* For treatment of moderate to severe *vasomotor* symptoms, atrophic vaginitis, or kraurosis vulvae associated with the menopause (0.3 to 1.25 mg or more daily).

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three to six month intervals.

2. *Given cyclically:* Female hypogonadism. Female castration. Primary ovarian failure. Osteoporosis.

Female hypogonadism—2.5 to 7.5 mg daily, in divided doses for 20 days, followed by a rest period of 10 days' duration. If bleeding does not occur by the end of this period, the same dosage schedule is repeated. The number of courses of estrogen therapy necessary to produce bleeding may vary depending on the responsiveness of the endometrium.

If bleeding occurs before the end of the 10 day period, begin a 20 day estrogen-progestin cyclic regimen with PREMARIN (Conjugated Estrogens Tablets, U.S.P.), 2.5 to 7.5 mg daily in divided doses, for 20 days. During the last five days of estrogen therapy, give an oral progestin. If bleeding occurs before this regimen is concluded, therapy is discontinued and may be resumed on the fifth day of bleeding.

Female castration and primary ovarian failure—1.25 mg daily, cyclically. Adjust upward or downward according to response of the patient. For maintenance, adjust dosage to lowest level that will provide effective control.

Osteoporosis (to retard progression)—1.25 mg daily, cyclically.

3. *Given for a few days:* Prevention of postpartum breast engorgement—3.75 mg every four hours for five doses, or 1.25 mg every four hours for five days.

4. *Given chronically:* Inoperable progressing prostatic cancer—1.25 to 2.5 mg three times daily.

Inoperable progressing breast cancer in appropriately selected men and postmenopausal women—10 mg three times daily for a period of at least three months.

Patients with an intact uterus should be monitored for signs of endometrial cancer and appropriate measures taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

PREMARIN® Brand of Conjugated Estrogens, U.S.P. Vaginal Cream

Given cyclically for short-term use only: For treatment of atrophic vaginitis or kraurosis vulvae.

The lowest dose that will control symptoms should be chosen and medication should be discontinued as promptly as possible.

Administration should be cyclic (e.g., three weeks on and one week off).

Attempts to discontinue or taper medication should be made at three to six month intervals.

Usual dosage range: 2 to 4 g daily, intravaginally or topically, depending on the severity of the condition.

Treated patients with an intact uterus should be monitored closely for signs of endometrial cancer and appropriate diagnostic measures should be taken to rule out malignancy in the event of persistent or recurring abnormal vaginal bleeding.

HOW SUPPLIED: PREMARIN (Conjugated Estrogens Tablets, U.S.P.). No. B65—Each *purple* tablet contains 2.5 mg in bottles of 100 and 1,000. No. B66—Each *yellow* tablet contains 1.25 mg in bottles of 100 and 1,000. Also in Cycle Pack of 21 and in unit dose package of 100. No. 864—Each *white* tablet contains 0.9 mg in bottles of 100. Also in Cycle Pack of 21. No. 867—Each *maroon* tablet contains 0.625 mg in bottles of 100 and 1,000. Also in Cycle Pack of 21 and unit dose package of 100. No. B68—Each *green* tablet contains 0.3 mg in bottles of 100 and 1,000. The appearance of these tablets is a trademark of Ayerst Laboratories.

PREMARIN (Conjugated Estrogens, U.S.P.) Vaginal Cream—No. B72—Each gram contains 0.625 mg Conjugated Estrogens, U.S.P. (Also contains cetyl esters wax, cetyl alcohol, white wax, glyceryl monostearate, propylene glycol monostearate, methyl stearate, phenylethyl alcohol, sodium lauryl sulfate, glycerin, and mineral oil.)

Combination package: Each contains Net Wt. 1½ oz. (42.5 g) tube with one calibrated plastic applicator.

Also Available—Refill package: Each contains Net Wt. 1½ oz. (42.5 g) tube. **4340R2/785**

ANNOUNCING SOME NEW FINDINGS ON CHOLESTEROL.

Perhaps rather surprisingly, beef has no more cholesterol than chicken. Even roast chicken without skin.

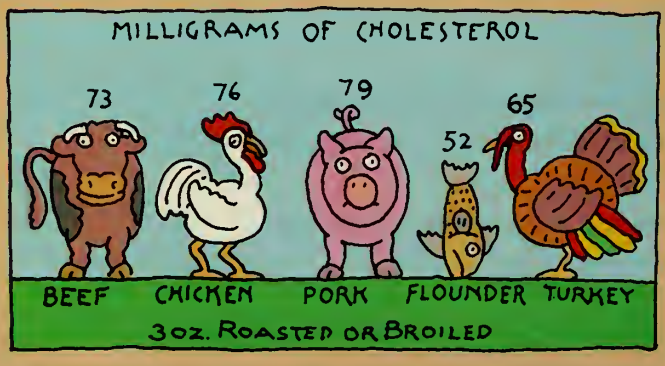
That was the finding of a new U.S.D.A. study on beef nutrient composition.*

That same study found beef is lower in calories than ever.

And lower in fat.

In fact, three ounces of beef now has just 192 calories and a modest nine grams of fat, over half of which is unsaturated.

Today, new breeding and feeding techniques are making beef a whole different animal. Though not so different that it isn't still one of the body's bes sources of iron, zinc, B-vitamins and protein.



It all means moderate portions of beef can fit easily int a reduced cholesterol, low saturated fat diet.

And that can stop a lot of squawking when you recommend one.

For more information on the new U.S.D.A. study and beef's contribution to healthy eating in the eighties, write to Beef Nutrition, California Beef Council, 551 Foster City Boulevard, Suite A, Foster City, California 94404.

*Beef data from 1983 Beef Nutritive Composition Studies conducted by the U.S.D.A. and National Live Stock and Meat Board.

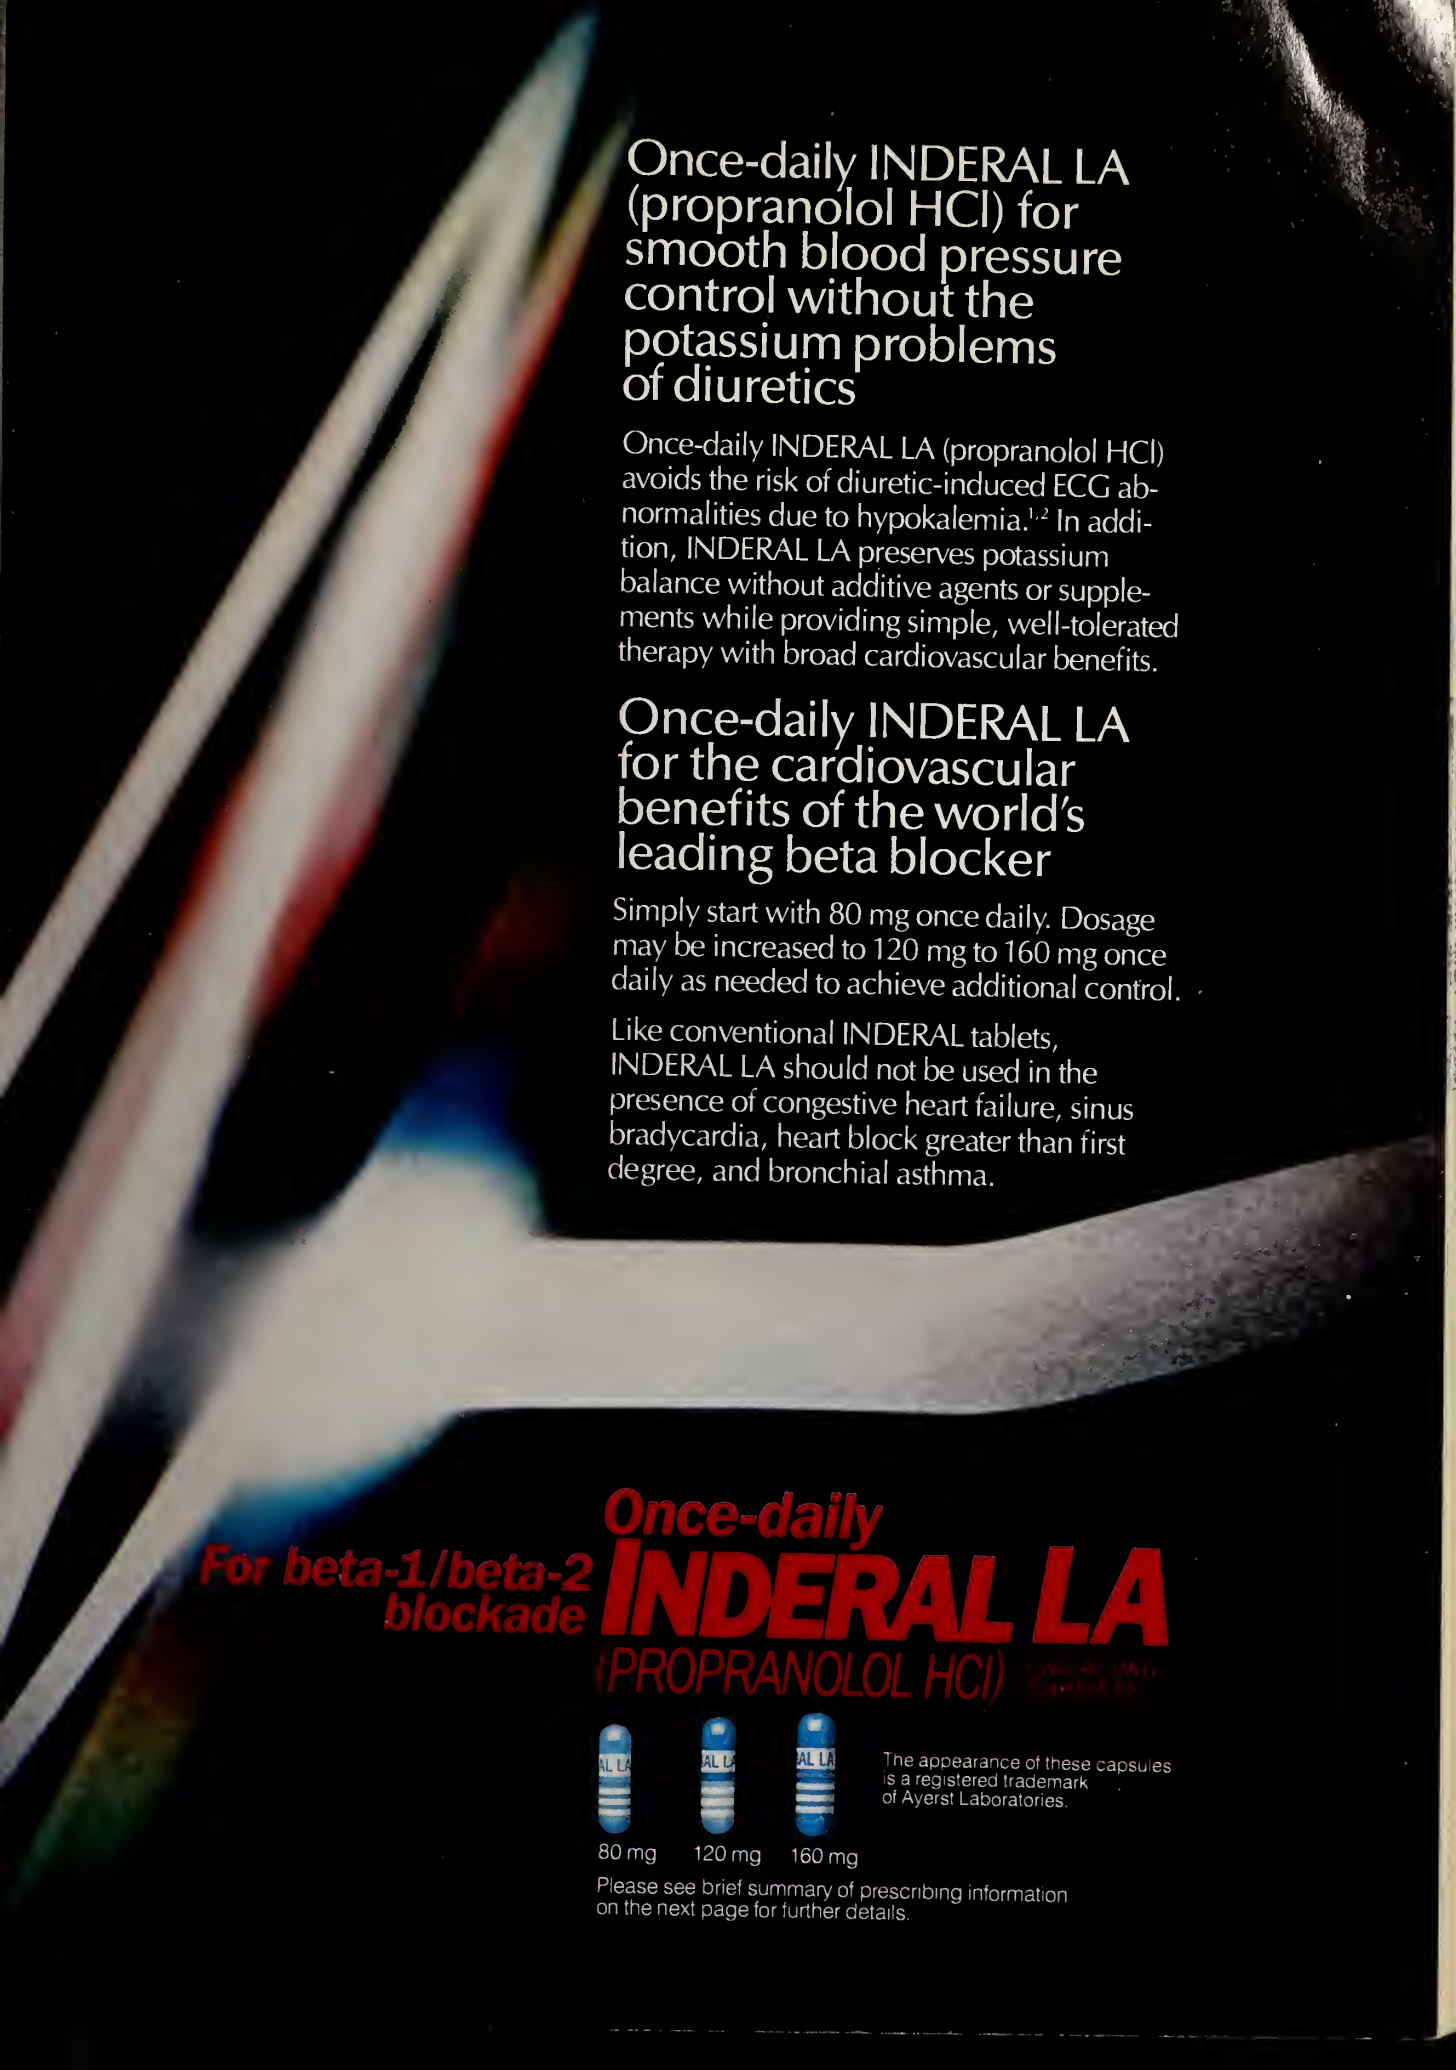
Right from the start in hypertension...



Once-daily INDERAL LA (propranolol HCl) for smooth blood pressure control without the potassium problems of diuretics
Once-daily INDERAL LA (propranolol HCl) avoids the risk of diuretic-induced ECG abnormalities due to hypokalemia.[1,2] In addition, INDERAL LA preserves potassium balance without additive agents or supplements while providing simple, well-tolerated therapy with broad cardiovascular benefits.
Once-daily INDERAL LA for the cardiovascular benefits of the world's leading beta blocker
Simply start with 80 mg once daily. Dosage may be increased to 120 mg to 160 mg once daily as needed to achieve additional control.
Like conventional INDERAL tablets, INDERAL LA should not be used in the presence of congestive heart failure, sinus bradycardia, heart block greater than first degree, and bronchial asthma.
For beta-1/beta-2 blockade
Once-daily
INDERAL LA
(PROPRANOLOL HCl)
The appearance of these capsules is a registered trademark of Ayerst Laboratories.
80 mg
120 mg
160 mg
Please see brief summary of prescribing information on the next page for further details.

"When it comes to cardiovascular medicine, I like to know exactly what my patients are swallowing."

INDERAL® Tablets

BRAND OF PROPRANOLOL HCl

10 mg 20 mg 40 mg 60 mg 80 mg 90 mg*

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION SEE PACKAGE CIRCULAR.)

INDERAL® (propranolol hydrochloride) Tablets

CONTRAINDICATIONS

INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma, 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS

CARDIAC FAILURE. Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely; or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY. The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA. Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS. Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS

General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL (propranolol hydrochloride) may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests. Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS. Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility. Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy. Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia, congestive heart failure, intensification of AV block, hypotension; paresthesia of hands, thrombocytopenic purpura; arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

NEW PROGRAMS

West Coast Counties
Monterey Sheraton
October 24-26, 1985

San Joaquin Valley Counties
Curry Village, Yosemite
April 17-19, 1986

TOPICS

- Practical Dermatology
- Update on AIDS
- Update on Hepatitis
- Current Antibiotic Therapy
- Quackery and Cancer in California
- Diabetes Management
- Cancer Chemotherapy
- Issues in Immunization
- Update for Primary Care Physicians

The content of these programs has been determined by the educational needs of primary care physicians as perceived and translated by the members of the Planning Committee.

***

These programs are accredited for Category One credit for Physicians and Registered Nurses

***

Hotel space is limited — early reservations are suggested.

***

Complete program and hotel information will be sent by return mail.
Use the tear off sheet below or call CMA 415/863-5522. extension 416.

WJ08/85

I plan to attend the following Postgraduate Institute(s):

☐ West Coast Counties
October 24-26, 1985
Monterey Sheraton

☐ San Joaquin Valley Counties
April 17-19, 1986
Curry Village, Yosemite

FEE: $125 for each institute
($200 for Non-CMA members)

Please make check payable to
California Medical Association

Attention: Janice Rigney

A program and hotel reservation form will be sent to you.

BALANCED CALCIUM CHANNEL BLOCKADE!

Low incidence of side effects
CARDIZEM® (diltiazem HCl) produces an incidence of adverse reactions not greater than that reported with placebo therapy, thus contributing to the patient's sense of well-being.

Reduces angina attack frequency*
42% to 46% decrease reported in multicenter study.[1]

Increases exercise tolerance*
In Bruce exercise test,[2] control patients averaged 8.0 minutes to onset of pain; Cardizem patients averaged 9.8 minutes ($P<.005$).

*Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm and in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

CARDIZEM®
(diltiazem HCl)

THE BALANCED CALCIUM CHANNEL BLOCKER

Please see full prescribing information on following page.

2/84

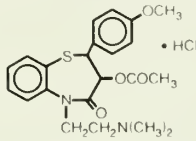
FRANCIS A. COUNTWAY LIBRARY OF MEDICINE

PROFESSIONAL USE INFORMATION

cardizem®
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM® (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy) -5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem hydrochloride for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanisms of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance, probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate-blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 2.0 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given, a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina. CARDIZEM has been effective in controlled trials in reducing angina frequency and increasing exercise tolerance.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block except in the presence of a functioning ventricular pacemaker, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (six of 1243 patients for 0.48%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg of diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** In rare instances, patients receiving CARDIZEM have exhibited reversible acute hepatic injury as evidenced by moderate to extreme elevations of liver enzymes. (See PRECAUTIONS and ADVERSE REACTIONS.)

PRECAUTIONS

General. CARDIZEM (diltiazem hydrochloride) is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS).

Controlled and uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities. In healthy volunteers, diltiazem has been shown to increase serum digoxin levels up to 20%.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

The following represent occurrences observed in clinical studies which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are: edema (2.4%), headache (2.1%), nausea (1.9%), dizziness (1.5%), rash (1.3%), asthenia (1.2%), AV block (1.1%). In addition, the following events were reported infrequently (less than 1%) with the order of presentation corresponding to the relative frequency of occurrence.

Cardiovascular:	Flushing, arrhythmia, hypotension, bradycardia, palpitations, congestive heart failure, syncope.
Nervous System:	Paresthesia, nervousness, somnolence, tremor, insomnia, hallucinations, and amnesia.
Gastrointestinal:	Constipation, dyspepsia, diarrhea, vomiting, mild elevations of alkaline phosphatase, SGOT, SGPT, and LDH.
Dermatologic:	Pruritus, petechiae, urticaria, photosensitivity.
Other:	Polyuria, nocturia.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

The following postmarketing events have been reported infrequently in patients receiving CARDIZEM: erythema multiforme; leukopenia; and extreme elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK. However, a definitive cause and effect between these events and CARDIZEM therapy is yet to be established.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experience with oral diltiazem has been limited. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered.

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. Although individual patients may respond to any dosage level, the average optimum dosage range appears to be 180 to 240 mg/day. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents:

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy** — CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

Cardizem 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1771-49). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47) and in Unit Dose Identification Paks of 100 (NDC 0088-1772-49). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

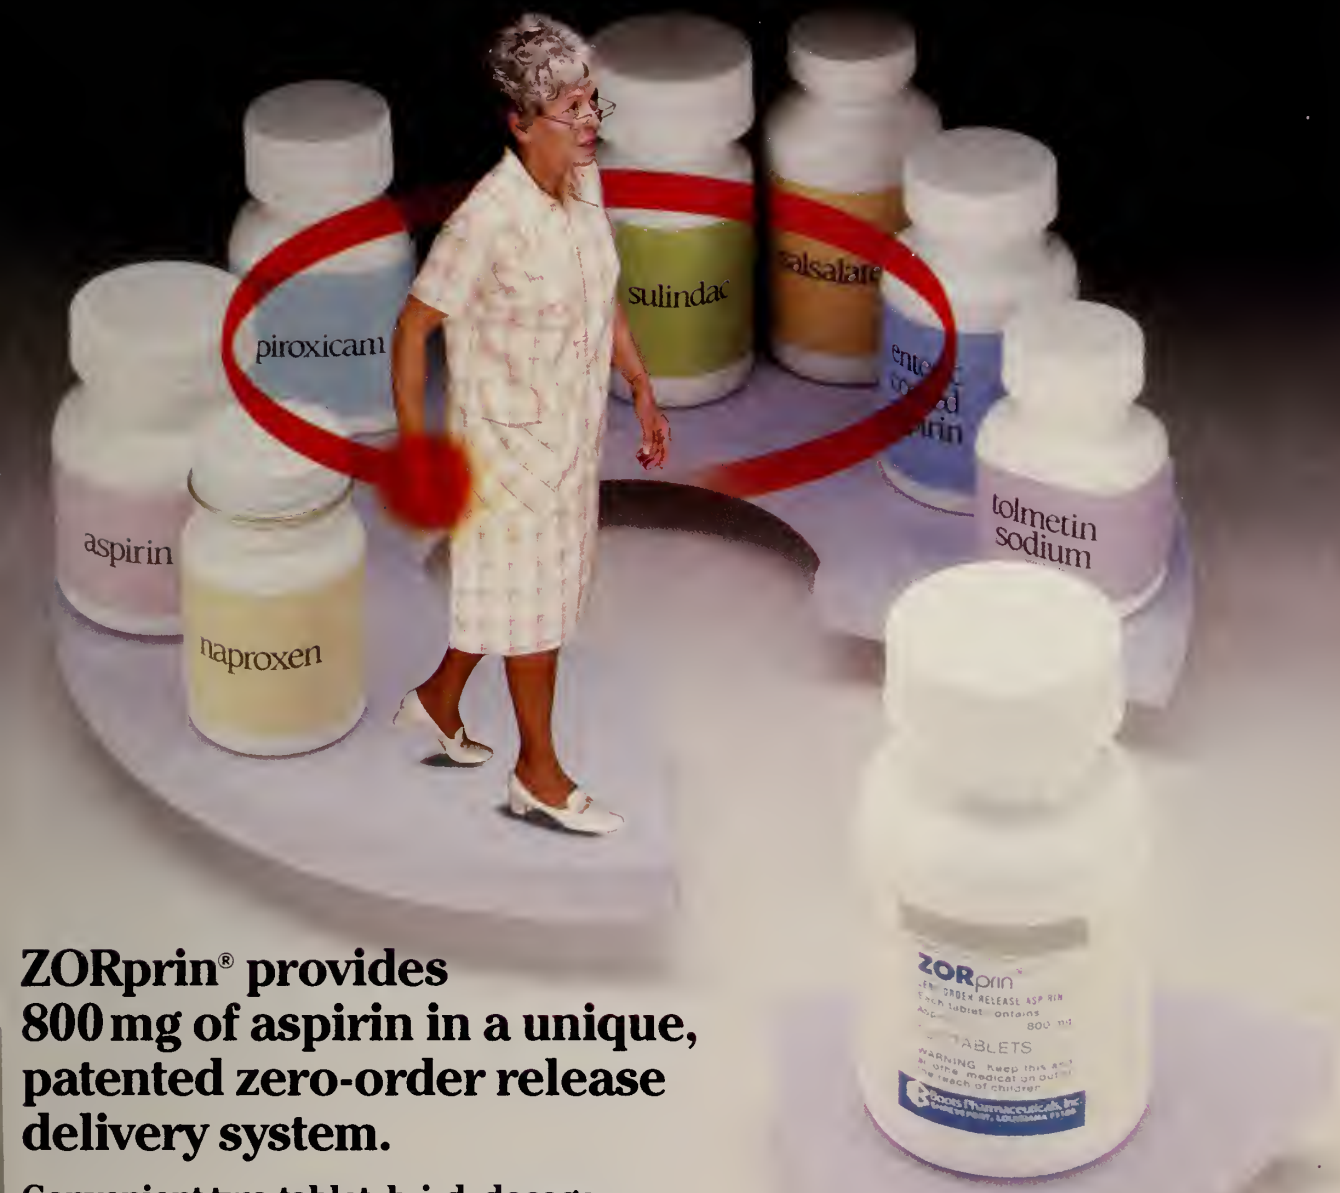
Put ZORprin (ASPIRIN) Zero-Order Release in your circle of arthritic therapy



ZORprin® provides 800 mg of aspirin in a unique, patented zero-order release delivery system.

Convenient two-tablet, b.i.d. dosage
- Easy-to-remember regimen improves compliance
- 24-hour pain relief

Efficacy comparable to NSAIs
- Helps reduce morning stiffness and nighttime pain

Side effect profile superior to plain aspirin... comparable to NSAIs
- ZORprin® is economical arthritic therapy
- Prescription only

The ideal method to maintain therapeutic control

Pioneers in medicine for the family

SHREVEPORT, LOUISIANA 71106-9989

See brief summary of prescribing information on next page.

ZORprin (aspirin) ZERO-ORDER RELEASE

Before prescribing see complete prescribing information. The following is a brief summary ▫ **INDICATIONS AND USE**: ZORprin® is indicated for the treatment of rheumatoid arthritis and osteoarthritis. The safety and efficacy of ZORprin® have not been established in those rheumatoid arthritic patients who are designated by the American Rheumatism Association as Functional Class IV, (incapacitated, largely or wholly bedridden, or confined to wheelchair, little or no self-care) ▫ **CONTRAINDICATIONS**: ZORprin® should not be used in patients known to be hypersensitive to salicylates or in individuals with the syndrome of nasal polyps, angioedema, bronchospastic reactivity to aspirin, renal or hepatic insufficiency, hypoprothrombinemia or other bleeding disorders. ZORprin® is not recommended for children under 12 years of age; it is contraindicated in all children with fever accompanied by dehydration ▫ **WARNINGS**: ZORprin® should be used with caution when anticoagulants are prescribed concurrently, since aspirin may depress the concentration of prothrombin in plasma and increase bleeding time. Large doses of salicylates may have hypoglycemic action and enhance the effect of the oral hypoglycemics, concomitant use therefore is not recommended. However, if such use is necessary, dosage of the hypoglycemic agent must be reduced. The hypoglycemic action of the salicylates may also necessitate adjustment of the insulin requirements of diabetics. While salicylates in large doses have a uricosuric effect, smaller amounts may reduce the uricosuric effect of uricosuric agents ▫ **USE IN PREGNANCY**: Aspirin can cause fetal harm when administered to pregnant women. Aspirin interferes with maternal and infant blood clotting and may lengthen the duration of pregnancy and parturition. Aspirin has produced teratogenic effects and increases the incidence of stillbirths and neonatal deaths in animals. If this drug is used during pregnancy, or if the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus. Aspirin should not be taken during the last 3 months of pregnancy ▫ **PRECAUTIONS**: Appropriate precautions should be taken in prescribing ZORprin® for patients who are known to be sensitive to aspirin or salicylates. Particular care should be used when prescribing this medication for patients with erosive gastritis, peptic ulcer, mild diabetes or gout. As with all salicylate drugs, caution should be exercised in prescribing ZORprin® for those patients with bleeding tendencies or those on anticoagulant drugs. Large doses of salicylates should be avoided in patients with clear evidence of carditis. In order to avoid exacerbation of disease or adrenal insufficiency, patients who have been on prolonged corticosteroid therapy should have their therapy tapered slowly rather than discontinued abruptly when ZORprin® (aspirin) is made a part of the treatment program. Patients receiving large doses of aspirin and/or prolonged therapy may develop mild salicylate intoxication (salicylism) that may be reversed by reduction in dosage. Salicylates can produce changes in thyroid function tests. Salicylates should be used with caution in patients with severe hepatic damage, preexisting hypoprothrombinemia, Vitamin K deficiency and in those undergoing surgery. Since aspirin release from ZORprin® is pH dependent, it may change in those conditions where the gastric pH has been increased via antacids, gastric secretion inhibitors or surgical procedures ▫ **ADVERSE REACTIONS**: **Hematologic**: Aspirin interferes with blood clotting. Patients with a history of blood coagulation defects or receiving anti-coagulant drugs or with severe anemia should avoid ZORprin® Aspirin used chronically may cause a persistent iron deficiency anemia. **Gastrointestinal**: Aspirin may potentiate peptic ulcer, and cause stomach distress or heartburn. Aspirin can cause an increase in occult bleeding and in some patients massive gastrointestinal bleeding. However, the greatest release of active drug from ZORprin® is designed to occur in the small intestine over a period of time. This has resulted in less symptomatic gastrointestinal side effects. **Allergic**: Allergic and anaphylactic reactions have been noted when hypersensitive individuals have taken aspirin. The most common allergic reaction to aspirin is the induction of bronchospasm with asthma-like symptoms. Other reactions are hives, rash, angioedema, as well as rhinitis and nasal polyps. Fatal anaphylactic shock, while not common, has been reported. **Central Nervous System**: Taken in overdoses, aspirin provides stimulation which may be manifested by tinnitus. Following initial stimulation, depression of the central nervous system may be noted. **Renal**: Aspirin may rarely cause an increase in the severity of chronic kidney disease. **Hepatic**: High doses of aspirin have been reported to produce reversible hepatic dysfunction ▫ **OVERDOSAGE**: Overdosage, if it occurs, would produce the usual symptoms of salicylism, tinnitus, vertigo, headache, confusion, drowsiness, sweating, hyperventilation, vomiting or diarrhea. Treatment for mild intoxication, emptying the stomach with an emetic, or gastric lavage with 5% sodium bicarbonate. Individuals suffering from severe intoxication should, in addition, have forced diuresis by intravenous infusions of saline and sodium bicarbonate or sodium lactate, dextrose solution. In extreme cases, hemodialysis or peritoneal dialysis may be required ▫ **HOW SUPPLIED**: ZORprin® tablets 800 mg, plain, white capsule-shaped tablets. Bottles of 100 tablets ▫ **CAUTION**: Federal Law prohibits dispensing without prescription. Manufactured and distributed by: Boots Pharmaceuticals, Inc. Shreveport, LA, 71106 USA.

"When that summons came, I was glad I had SCPIE.

"My reputation was on the line, but SCPIE had the right people to handle everything.

"They know how to protect a physician."

Experience and strong physician management help make SCPIE Number One.

SCPIE is the largest Medical Association/Society-sponsored, physician-owned writer of claims made professional liability insurance in the nation!

This means:

Rates at the lowest possible level consistent with a stable company. The physician gets back premium dollars, plus investment income, not needed to pay claims and costs.

Already insured?

Ask about SCPIE's nose coverage. It lets qualified physicians move from another claims made carrier without paying "tail" coverage to the prior company. You join SCPIE at a premium commensurate with your rate and years of coverage under the prior plan.

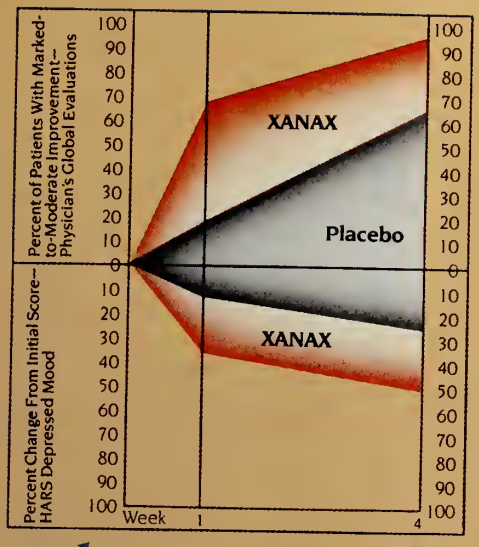
anxious
geriatrics...
Anxiety and
depressive
symptoms
go hand
in hand.

Xanax rapidly relieves anxiety with depressive symptoms.



In a recent clinical study[1] of 83 geriatric patients with clinical anxiety, 73% were diagnosed as having symptoms of depressed mood.

XANAX is well suited for therapy because it demonstrates greater efficacy than placebo in reducing the Hamilton Anxiety Rating Scale Total Score and individual items including depressed mood (see Figure).

With clinical advantages for geriatric patients.

- **Rapidly relieves** the symptoms of anxiety
- **Rapidly relieves** associated depressed mood
- **Well tolerated**—mild, transient drowsiness, the most commonly reported side effect the first week of therapy, shows a marked decrease thereafter and is not significantly different from that of placebo
- **Does not cause** cardiotoxicity
- **Specific geriatric dosage**—0.25 mg, two or three times daily

Please see next page for brief summary of prescribing information.

XANAX® Tablets
(alprazolam) ℞

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation. (See Drug Interaction section.) Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage. (See Dosage and Administration.) Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other side effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

DOSAGE AND ADMINISTRATION
The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than one milligram every three days.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

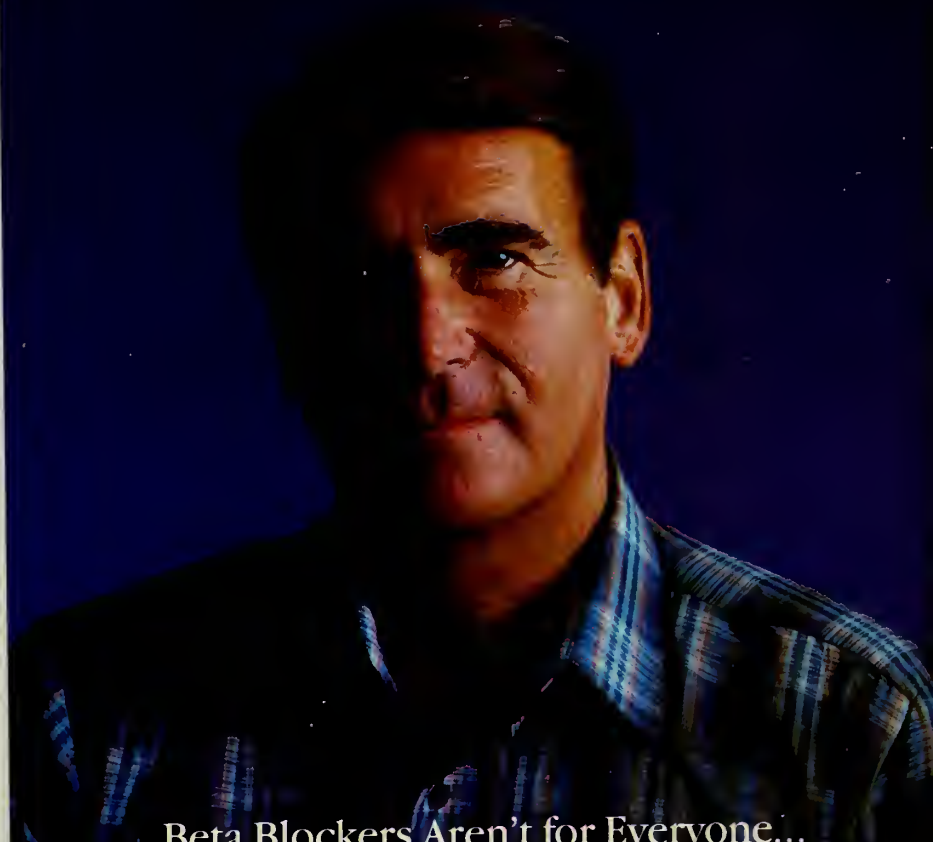
(Continued on Page 282)

In Hypertensives Over 50, Diuretics Are Preferred

The 1984 Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure recommends diuretics as the favored monotherapy in patients over 50 years of age, regardless of sex or race.



Beta Blockers Aren't for Everyone...

For Hypertensive Patients* Over 50

PRESCRIBE

DYAZIDE®

25 mg Hydrochlorothiazide/**50 mg** Triamterene/SKF

Used with Confidence for over 19 Years

Serum K^+ and BUN should be checked periodically (see Warnings and Precautions).

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. Associated widened QRS complex or arrhythmia requires prompt additional therapy. Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: The bioavailability of the hydrochlorothiazide component of 'Dyazide' is about 50% of the bioavailability of the single entity. Theoretically, a patient transferred from the single entities of Dyrenium (triamterene, SK&F CO.) and hydrochlorothiazide may show an increase in blood pressure or fluid retention. Similarly, it is also possible that the lesser hydrochlorothiazide bioavailability could lead to increased serum potassium levels. However, extensive clinical experience with 'Dyazide' suggests that these conditions have not been commonly observed in clinical practice. Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

Supplied: 'Dyazide' is supplied as a red and white capsule, in bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

Clinical Investigation

Comparison of Flow Rates for Standard and Large-Bore Blood Tubing

KENNETH V. ISERSON, MD; ALAN K. REETER, MSEE, CCE, *and* ELIZABETH CRISS, RN, *Tucson*

One of the clinically significant rate-limiting components in even the fastest of intravenous (IV) fluid systems is the tubing connecting the IV catheter to the IV solution container. We evaluated the effect large-bore tubing has on reducing this limitation on fluid flow, measuring gravity and pressurized flow in standard and large-bore tubing alone and when each was connected to an 8 French and 12-, 14- and two types of 16-gauge catheters. When combined with an 8 French catheter, large-bore tubing produces a 126% increase in flow under gravity and a 90% increase under pressure. The improvement with the large tubing was less significant as the catheter size decreased. Studies in normovolemic adult volunteers achieved similar results. Large-bore blood tubing and large-bore catheters should be used in all situations where the need for rapid fluid replacement is contemplated.

(Iserson KV, Reeter AK, Criss E: Comparison of flow rates for standard and large-bore blood tubing [Clinical Investigation]. West J Med 1985 Aug; 143:183-185)

The need for rapid volume replacement in cases of traumatic or nontraumatic exsanguination is well recognized.[1-4] This recognition has produced a variety of methods designed to quickly infuse fluids intravenously (IV) to such patients.[1-7] However, one of the rate-limiting components in even the fastest system is the tubing connecting the catheter to the IV bag. Recently, a large-diameter IV tubing has become commercially available in the United States.

We compared the flow rates of this large-bore blood tubing with standard IV blood tubing. The results indicate that the large-bore tubing is a significant new tool for hypovolemic resuscitation. Clinical trials using the largest catheter-tubing combination in normovolemic human subjects also confirm this conclusion.

Methods

Large-bore blood tubing (Fenwal Laboratories, Deerfield, IL 60015, #4C2194) and standard blood tubing (Delmed Y-Blood Solution Set, #03-122-00) were studied. The large-bore tubing had an internal diameter of approximately 3.66 mm (11 French) and was 220 cm long. The standard tubing had an internal diameter of 3 mm (9 French) and was 230.5 cm long.

Utilizing gravity and a constant pressure of 300 mm of mercury, flow rates were measured for each type of tubing. The rates were determined for each type of tubing alone and for each type of tubing in combination with five catheters: 8 French (Universal Medical Instrument, Inc, Ballston Spa, NY 12020), 12 gauge (Vygon, Laboratoires Pharmaceutiques, BP-7 95440 Ecoven, France), 14 gauge (Travenol Laboratories, Deerfield, IL 60015), 16 gauge (Vygon) and 16 gauge (Travenol). Each measurement began with a vertical distance of 91.44 cm (3 ft) between the fluid level in the IV bag and the catheter tip. A glass graduated cylinder (KIMAK, TD 20°C, #20024) was used for measurement. A flow rate was calculated for each tubing and tubing-catheter combination by timing the flow of a series of three 400-ml aliquots of 5% dextrose in water USP.

Following these in vitro experimentations, three normovolemic male volunteers were given 1,000 ml of fluid in two timed 500-ml aliquots using the 12-gauge-large-bore tubing combination under pressure. The basilic or cephalic vein in the antecubital fossa was the site of placement for the catheter.

Results

We measured the gravity flow rates for the standard blood tubing and large-bore tubing alone and when each was connected to 8 French and 12-, 14-, and two types of 16-gauge catheters (Table 1). The standard tubing alone produced a mean flow rate of 173 ml per minute and rates of 171, 169,

134, 102 (Vygon) and 88 (Travenol) ml per minute, respectively, when combined with the various catheters. The large-bore tubing alone had a rate of 414 ml per minute and with the catheters produced mean flow rates of 387, 333, 211, 136 (Vygon) and 110 (Travenol) ml per minute, respectively.

We also measured the flow rates under pressure using the same tubing and tubing-catheter combinations. The flow rates with the standard tubing and tubing-catheter combinations were 571, 545, 522, 429, 324 (Vygon), and 270 (Travenol) ml per minute, respectively. The flow rates for the large-bore tubing and tubing-catheter combinations were 1,263, 1,043, 889, 500, 369 (Vygon) and 333 (Travenol) ml per minute, respectively.

The measured flow rates using the 12-gauge catheter and large-bore tubing under pressure in the human subjects averaged 848 ml per minute (range, 818 ml per minute to 870 ml per minute).

Discussion

The steady laminar flow rate of incompressible fluid through circular tube is proportional to the fourth power of the radius, as described in Poiseuille's law:

$$Q = \frac{\pi r^4 (\Delta P/L)}{\eta 8}$$

where Q = rate of flow, r = tube radius, $\Delta P/L$ = pressure gradient and η = dynamic fluid viscosity.

Ideally, then, without a catheter the larger tubing should have a flow rate 2.2 times that of standard IV tubing. In our tests using a pressure of 300 mm of mercury, the large-bore tubing alone actually did produce an increased flow rate 2.2 times that of the small tubing. In the gravity tests, however, it produced an increased flow rate 2.4 times that of the small tubing. While seemingly paradoxical, two factors came into play. First, the flow in the small tubing, because of its narrow diameter, was almost certainly inhibited by increased turbulence. Second, in the pressurized systems the flow rate was probably not as great because increased fluid velocity alone tends to create more turbulence. Increased turbulence causes the system to perform below theoretic predictions.

When combined with the largest catheter, the large-bore tubing improved the flow rate by 126% under gravity and 90% under pressure. While the improvement in flow rates with the large-bore tubing is substantial, it is less than that predicted by Poiseuille's law. Yet it is a clinically significant improvement for a severely hypovolemic patient.

When small catheters are used with the large-bore tubing, they become the primary limiting factor for fluid flow. As catheter size was decreased in this study, the effect of tubing size became less significant. With the smallest catheter the large-bore tubing improved the flow rate by only 25% under gravity and 23% under pressure. Therefore, using the large-bore tubing with these catheters is not a cost-effective alternative.

The significant differences among the various brands of 16-gauge catheters are consistent with prior reports.[4,5]

Significantly, no appreciable differences were found in vitro between the flow rates of the peripheral 12-gauge and the central 8 French catheters which, in fact, have a very similar internal diameter. Therefore, percutaneous peripheral insertion of the 12-gauge catheter should be a suitable alternative to the potentially dangerous central vein catheterization.[8]

In normovolemic human subjects, a flow rate decrease consistent with fluid flow theory (Poiseuille's law) occurred when using the 12-gauge catheter-large-bore tubing combination under pressure. With an estimated backpressure of 15 to 18 mm of mercury in the peripheral venous system, there was a proportional decrease in fluid flow. This decrease is expected because of a linear relationship between the pressure gradient (ΔP) and the rate of fluid flow. Despite this 5% to 6% decrease in flow rate, a clinically significant amount of fluid was safely and quickly infused with this combination.

Based on the results of this study, it seems clear that large-bore blood tubing and a large catheter should be used in

all situations where the need for rapid fluid replacement is contemplated. In addition, our data suggest that the use of the peripheral 12-gauge catheter may be an alternative to the more complication-prone large central catheter.

Medical Practice Question

EDITOR'S NOTE: *From time to time medical practice questions from organizations with a legitimate interest in the information are referred to the Scientific Board by the Quality Care Review Commission of the California Medical Association. The opinions offered are based on training, experience and literature reviewed by specialists. These opinions are, however, informational only and should not be interpreted as directives, instructions or policy statements.*

Heart-Lung Transplantation

QUESTION:

Is heart-lung transplantation considered acceptable medical practice or is it considered investigational?

OPINION:

In the opinion of the Scientific Advisory Panels on Chest Diseases, General Surgery and Internal Medicine and the Ad Hoc Committee of Organ and Tissue Transplantation, heart-lung transplantation cannot be considered standard medical practice at the present time. This procedure is still under investigation and should be restricted to those institutions that have shown the necessary skills, resources (both clinical and research) and institutional commitment to manage the patient's total preoperative and postoperative care. The number of such centers is few.

General advances in immunosuppression and patient selection have contributed to the successful short-term survival of the small number of patients who have received heart-lung transplants. However, a larger number of patients is required to confirm the preliminary results and document long-term survivial.

To date, patients with irreversible pulmonary vascular disease either of a primary nature or secondary to cardiac defects have been the best candidates for heart-lung transplantation.

Risk Factors in Stroke

PIERO MUSTACCHI, MD, *San Francisco*

In the United States, stroke accounts for 160,000 annual deaths; only 16% of the 1.8 million stroke survivors are fully independent. The incidence of stroke increases with age. Hemorrhagic strokes outnumber ischemic strokes before age 15. Japanese men in this country have a lower stroke mortality than their age peers in Japan. Excessive stroke mortality for US nonwhites may not be entirely due to the greater prevalence of hypertension among blacks. Hypertension emerges as the single most powerful and reversible risk factor in stroke and for survival after stroke. Impaired cardiac function is the second most important precursor of stroke. The recurrence of stroke in survivors is high. The frequency of completed stroke is high in persons with transient ischemic attacks, but not in those with asymptomatic carotid bruits. Other reversible risk factors are smoking, the use of oral contraceptives, alcoholic excess, a low level of physical activity, blood hyperviscosity and drug abuse.

(Mustacchi P: Risk factors in stroke. West J Med 1985 Aug; 143:186-192)

From 13% to 20% of the cardiac output goes to the brain,[1] an organ that represents only 2% of total body weight.[2] Cerebral blood flows normally at a rate of 40 to 45 ml per 100 grams of brain per minute. Considerable reduction in flow can occur before a deficit becomes clinically significant. The ischemic tolerance of neural tissue is proportional to the severity and duration of flow reduction.[3] At zero flow (cardiac arrest), this tolerance is about four minutes.[4] A blood flow of 18 ml per 100 grams per minute at an arterial carbon dioxide pressure of 40 torr can temporarily sustain a normal electroencephalogram.[3] Electroencephalographic changes and presumably ischemic symptoms develop at blood flow rates below 17 ml per 100 grams per minute.[3] A further decrease in flow to less than 10 ml per 100 grams per minute results in permanent brain tissue infarction.[5]

The current definition of stroke stipulates that the focal diagnostic neurologic deficits such as hemiparesis, aphasia or homonymous hemianopia be of abrupt or rapid onset; if not fatal, the deficit should last more than 24 hours. The definition also specifies that the vascular origin be limited to either thrombotic or embolic occlusion of a cerebral artery or to spontaneous rupture of a vessel resulting in intracerebral or subarachnoid hemorrhage. The definition excludes changes due to vascular lesions of clearly traumatic, neoplastic or infectious orgin.

Although mortality from stroke has been steadily declining,[6-14] it still accounts for 16% of all deaths in the United States.[15] In addition to the 160,000 annual stroke deaths, more than ten times as many (some 1.8 million persons) survive stroke with varying levels of residual disability.[15] Among the survivors, cerebral infarction reduces the proportion of those who were completely independent from 57% before infarction to 16% after infarction.[13] Aphasia alone is an important residual incapacity in 10%.[16]

General Risk Factors

Developmental Factors

Intracranial hemorrhage. Intracranial hemorrhage that occurs later in life can be due to bleeding "berry" aneurysms.[17] That many aneurysms become symptomatic around age 20 or later suggests that unidentified developmental factors are at play. A statistically valid association links berry aneurysms to coarctation of the aorta and to polycystic kidneys.[18] Subarachnoid hemorrhage was the cause of death in 22% in a study of persons with polycystic kidneys.[19]

Intracranial hemorrhage, whether subarachnoid or intracerebral, may be the first manifestation of atrioventricular malformations that had been silent until early maturity. Bleeding may follow as late as a decade after an initial convulsive seizure suffered during early adolescence.

When developmental defects lead to asymmetric growth, the smaller vessels are more likely to occlude. Of 17 patients with severe asymmetric carotid stenosis, 13 had greater stenosis on the side of the smaller vessels.[19]

Hemorrhagic strokes. Hemorrhagic strokes outnumber ischemic strokes 3:1 in children younger than 15 years, with a

combined average annual incidence rate of 2.52 per 100,000.[20] After maturity the reverse is true.[21,22] The incidence rate for stroke increases progressively with age[13,23-25] as atherosclerotic plaques and internal thickness of the basilar artery and the anterior cerebral arteries increase. In the anterior cerebral arteries, the onset of the first atherosclerotic plaques lags by about ten years behind similar formations in the basilar artery.[26]

At birth, elastin in the arteries of the circle of Willis and its large branches is concentrated in the internal elastic layer, in contrast to muscular arteries of other organs whose media and adventitia contain abundant elastic fibers in the outer layer.[27] Increasing amounts of elastic tissue can be found in the external layer of the cerebral arteries until age 2. Thereafter, the density of the elastic fibers seems to decrease until, after age 30, few fibers are still visible. This age-related change in proportion of elastin has been attributed to altered biochemical composition indicative of a concomitant dysfunction.[27]

Sex

Coronary heart disease affects predominantly men, but the sex differential is not so pronounced in cases of stroke.[6,10,28-31] In some age groups and in American blacks,[32] there is a slight excess in the incidence of stroke in women.

Race

Mortality in Japanese and US nonwhites of all ages from vascular lesions of the nervous systems exceeds that of US whites at all ages.[32] Studies of emigrant Japanese suggest that the observed excess reflects environmental rather than genetic factors. American-Japanese men tend to have a lower stroke mortality than their peers in Japan.[33-35] Native Japanese men are significantly more likely to have intraparenchymal arteriosclerosis and cerebral infarction than Hawaiian Japanese.[36] Because the Japanese migration to Hawaii and California occurred mainly between 1880 and 1924, it is of interest that stroke mortality in American-Japanese had dropped nearly to the levels for whites by 1960, whereas their mortality from coronary heart disease remained intermediate.[35]

Nonwhite mortality from cerebrovascular diseases in the United States for persons aged 35 to 74 years has been about twice that of whites.[11,37] The greater prevalence of hypertension among blacks remains a mystery, as the higher rates could be attributed to incorrect death certification in states underserved by physicians,[38] or to underenumeration of the black population by census takers.[39]

Familial Clustering

Parental deaths from stroke,[40] cardiovascular-renal disease[41] or any cause[42] are overrepresented among stroke victims. Hypertension and cerebrovascular disease are significantly more frequent in monozygotic than in dizygotic twins of the same sex.[43]

Secular Trends

The past four revisions of the *International Classification of Diseases* introduced an element of uncertainty in the interpretation of long-term trends of stroke mortality.[6-8,28,44] Studies limited to data collected after the 1968 (most recent) revision concur in a downward mortality trend,[8,10] a pattern that emerges also from separate analyses of the four chronologic periods corresponding to the fifth through the eighth revisions.[11] The decline in stroke mortality that accelerated around the late 1960s[9,11,12] or the early 1970s[45] may even have been underestimated. Epidemiologic evidence indicates that the decline in mortality reflects a real decrease in stroke incidence.[16,45] The reduction in mortality for major cardiovascular diseases since 1965 far exceeds what could reasonably be explained by the decline in the changing autopsy rate since then.[46]

The reasons for the decline are unclear,[47] as it started long before effective antihypertensive therapy became widely available. An attractive hypothesis has correlated these changes in mortality with the declining use of salt.[48] If so, the changes in dietary habits made possible by the introduction of refrigeration and deep freezing may have proved one of the most important contributions to preventing stroke.[49]

Specific Risk Factors

Hypertension

Fixed and systolic hypertension. Hypertension emerges from prospective studies in Framingham (Massachusetts),[50,51] Chicago,[52] Honolulu,[53] Rochester (Minnesota),[54] Finland[55] and Japan[23] as the most common precursor of atherothrombotic brain infarction. The risk increases with elevated systolic and diastolic values,[37] the relationship being almost linear independently of age and sex.[51]

Elevated systolic pressure was highly predictive of subsequent stroke, even when not associated with diastolic elevations. Blood pressure values above 140/90 mm of mercury were recorded in all but 10 of the 105 stroke victims identified during the initial 18 years of the Framingham study. The normotensive persons who had contributed the ten cases of stroke had only one fourth of the stroke risk of their hypertensive counterparts.[51] Hypertension is a powerful predictor of atherosclerotic brain infarction when other factors such as gout, diabetes mellitus and obesity are excluded.[30] Systolic blood pressure values discriminated between susceptible and nonsusceptible persons and systolic and diastolic values used together.[30] In a retrospective study of the stroke mortality of former university students,[41] decedents had registered higher mean systolic and diastolic blood pressures when in college, and significantly more persons who had died of stroke (45%) than controls (31%) had had systolic blood pressure levels above 130 mm of mercury.[41] Japanese data have shown a correlation of systolic and diastolic hypertension and mean arterial pressure with the risk of stroke and that increasing values increase the risk for cerebral hemorrhage and cerebral infarction.[23] In cases of hypertension, the risk for atherothrombotic stroke is essentially the same as for hemorrhagic stroke.[33]

The contribution of hypertension to the risk of stroke is independent of arterial rigidity.[56] Oscillometric finger recordings in the Framingham study of 1,825 consecutive persons graded the depth of the dicrotic notch from absent to pronounced. Because the dicrotic notch is the combined result of rebound elastic recoil after aortic valve closure and such factors as the tone of smaller vessels and peripheral vascular resistance, peripheral vasoconstriction may cause the incisura to disappear. In the absence of peripheral vasoconstriction, aortic valve disease or heart failure, the incisura is largely a

reflection of arterial elasticity and arteriolar tone. Regression analysis of stroke incidence on age, systolic pressure and pulse-wave configuration indicates that the contribution of the pulse-wave is not significant, whereas that of systolic pressure has a high coefficient of correlation. This relationship obtains even though the elastic tissue in the arterial walls diminishes with age and contains more calcium, so that fewer aging persons have a normal pulse-wave tracing.

In persons older than 30 years, isolated systolic hypertension cannot be considered an innocent concomitant of aging inelastic arteries[57] but rather an often-neglected precursor of stroke,[56] hypertensive cardiac failure, coronary heart disease and occlusive peripheral arterial disease.[57] In monkeys, experimentally induced aortic coarctation resulted in systemic hypertension and in multifocal brain lesions at the capillary level. The pathologic changes that could be explained by successive episodes of regional ischemia or hyperperfusion (or both) resembled those seen in the brain of hypertensive humans.[58]

Labile hypertension. In contrast to the gravity of labile diabetes mellitus, labile hypertension is generally viewed either as the relatively benign manifestation of an exaggerated stress response or, at worst, a possible prelude to "fixed" hypertension.[59] Thus there is the tendency to disregard an elevated initial blood pressure reading and to repeat the measurement after the patient is relaxed.

In the Framingham cohort, hypertension was designated by two pressure determinations exceeding 160/95 mm of mercury. Normal tension was defined by values consistently below 140/90 mm of mercury and intermediate readings were considered borderline. It was found that higher pressures were more labile than lower ones, so that persons with fixed hypertension had more labile pressures than those with so-called labile hypertension. Lability also increased with age. For any given average pressure, the risk of cardiovascular events was unaffected by the degree of variability of the pressure. In other words, the higher the average reading, the greater the risk of cardiovascular complications. Rather than disregarding a single hypertensive reading and drawing reassurance from a subsequent normal basal pressure, to identify patients at risk for cardiovascular complications, one should rely on the average of several readings preferably taken on more than one occasion.[60]

Effect on prognosis. In prospective studies in the United States and Canada, survival after stroke was shorter in persons who had hypertension before stroke developed.[61,62]

Effect of treatment. In an Australian study based on regular biannual health screening of a small township, better control of blood pressure was associated with lesser stroke mortality in men aged 50 years and older, but not in women.[63] In a US double-blind study, only 6 cases of stroke occurred among hypertensive persons receiving antihypertensive drugs, whereas 25 cases of stroke occurred in the comparison group receiving a placebo.[64] The study also showed that stroke had occurred in patients whose diastolic pressure had not been reduced below 100 mm of mercury.[64] A study of 10,000 persons with hypertension in 14 cooperating centers confirmed that clinical control of hypertension protects against stroke,[65] especially in patients younger than 70 years. Among patients admitted to hospital for stroke, two thirds were known to have hypertension[66]; although most (91%) were treated with antihypertensive drugs, in the physicians' judgment, one in four had not been taking medications for two or more days. Almost a third of the study group had had diastolic readings above 105 mm of mercury on at least one occasion, with systolic values exceeding 180 mm of mercury at least once in almost half of them.

In Minnesota, a community hypertension control program increased from 40% to 76% the proportion of persons whose hypertension seemed adequately controlled.[67] These impressive results were associated with a declining incidence of and increased survival in cerebral infarction.[13]

Heart Diseases

After hypertension, impaired cardiac function is the most powerful precursor of stroke and atherothrombotic infarction.[68] Embolic stroke can be a complication of cardiac arrhythmia.

Atrial arrhythmias. Atrial arrhythmias will predispose to left atrial thrombus formation and cerebral embolization. Atrial fibrillation increases the risk of stroke sixfold; in the presence of rheumatic mitral disease, the risk increases 17-fold.[69] The annual incidence of cerebral embolization in the presence of sick sinus syndrome is 7.2%.[70] Atrial arrhythmias were identified during long-term electrocardiographic monitoring in 44% of patients with nonhemorrhagic stroke, twice the percentage in the reference population.[70]

Mitral valve prolapse. This valvular abnormality affects 5% of the general population.[71] It has been associated with the development of focal neurologic signs in young normotensive persons who had no overt coagulation defect and who were not using oral contraceptives.[71,72] Angiograms have suggested an embolic pathogenetic mechanism,[73] possibly mediated via platelet coagulant hyperactivity[74,75] or shortened survival time[76] or by newly recognized links between coagulation and cardiovascular disorders.[72]

Mitral valve prolapse was the only identifiable precursor in 5% to 30% of young adults with otherwise unexplained cerebral infarction,[77-80] but the actual risk of stroke in young adults with asymptomatic mitral valve prolapse seems rather low, possibly of the order of 1 in 6,000 per year.[78] During an observation period of some 3,800 person-years contributed by 760 patients with mitral valve prolapse, only one suffered a stroke,[81] suggesting an annual rate of 1.5 in 6,000. No prophylactic treatment seems warranted in asymptomatic persons with this valvular dysfunction.[78] Among persons with mitral valve prolapse, the prevalence of stroke is four times that observed in the general population.[82]

Hypertensive and atherosclerotic heart disease. The risk for atherothrombotic cerebral infarction is greatest among hypertensive persons with electrocardiographic[23,53] or radiologic evidence of cardiac involvement,[30] reflecting suboptimal cardiac output and reduced cerebral perfusion at the level of severely narrowed vessels.[30] A previous history of myocardial infarction almost trebles the risk of stroke (relative risk = 2.9).[25]

Effect on prognosis. Besides being risk factors, prestroke hypertension, coronary heart disease and congestive heart failure reduce the five-year survival rate for cases of brain infarction from 85% to 35% in men and from 70% to 56% in women.[66] The higher the systolic blood pressure before stroke, the higher the mortality.[62]

Previous Stroke

The Framingham study showed that the recurrence rate among stroke survivors is substantial.[61] Most recurrences are of the type of the previous stroke. Most strokes are atherothrombotic, reflecting the poor survival after the hemorrhagic ones. Men have a higher (42%) five-year cumulative recurrence rate than women (24%). The observed sex difference could reflect better control of hypertension and its complication in women.[61]

Transient Ischemic Attacks

The age-adjusted annual incidence rate for transient ischemic attack (TIA) is 31 in 100,000 in Rochester, Minnesota, where age-specific rates increase with advancing age and show a prominent jump after age 65.[83] In southern California, elderly persons with a history of transient focal or nonfocal cerebral ischemic symptoms carry an increased risk for the development of a completed stroke whether nonfocal symptoms such as spells of dizziness, syncope, vertigo or loss of balance were manifestations of vertebrobasilar ischemia or were caused by impaired cardiac function.[84] Both focal and nonfocal ischemic symptoms were significant and independent predictors of stroke.[84] The cumulative rates of completed stroke were 2.3% among those with focal and nonfocal symptoms, twice the value observed among an asymptomatic comparison group.[84] Patients who have had a TIA are at increased risk for stroke. During the first year after the initial attack, one group had 33 strokes versus the expected 2.[83] A lower relative risk for TIA-related stroke was reported among Hawaiian-Japanese in whom 2 strokes occurred instead of the 0.7 expected.[85]

The observed conditional probability of surviving free of stroke after the first TIA was 62% after five years and 50% after ten years, whereas 90% of the general population would have remained free of stroke for ten years.[83] Regardless of the anatomic source of TIAs, twice as many of the subsequent deaths were due to cardiac causes as to stroke.[86] Because of the accelerated total mortality associated with TIAs, only 25% rather than the expected 50% of a study cohort was still alive ten years after the initial TIA. A similarly accelerated mortality for cardiovascular illness and stroke was shared by a biracial population in Georgia who had symptomatic TIAs.[87] When nonfatal stroke and death were combined as an endpoint, there was no significant difference between the survival curves for vertebrobasilar insufficiency and carotid insufficiency in either men or women.[84]

The risk for ischemic stroke associated with TIAs is most increased in the presence of heart disease[54] and stenosis of large arteries. Stenosis is important mostly as a source of emboli because the arterial lumen of the internal carotid must be reduced by 80% to 90% before there is a significant effect on flow.[88] Both embolic and hemodynamic factors are important in the pathogenesis of TIAs; microemboli are more frequent in the carotids, and hemodynamic factors are of special importance in the vertebrobasilar system.[89]

Asymptomatic Carotid Bruits

As verified by Doppler findings, the hallmark of internal carotid artery stenosis is a high-pitched bruit best heard at the angle of the jaw.[90] In a review of seven prospective studies cumulating 703 persons with asymptomatic carotid bruits, it was concluded that the mean annual rate for completed stroke events is low, probably around 2%.[90] The side of the bruit often does not coincide with the side of the stroke, but this could simply mean that when both carotids are atherosclerotic, a bruit is heard over the least diseased artery.

Because of the low annual risk for stroke in these patients, it is recommended that if a corrective operation is to be done, it should be done in institutions where surgical risks are similarly low—that is, not exceeding 2% or 3% at most.[90] The risk of stroke in the region of a significant but asymptomatic carotid-bifurcation plaque was low (3%) in persons who had undergone contralateral endarterectomy for a TIA or a minor stroke.[91] Stroke was just as likely to develop either in the area of a previously operated carotid artery (5%) or in the vertebrobasilar area (4%).[91]

Other Observations

In a number of studies,[25,31,50,92,93] *impaired glucose tolerance* and *clinical diabetes* were identified as significant and consistent contributors to stroke risk, with an adjusted relative risk of 2.2.[25] At any level of blood pressure, the risk for atherothrombotic stroke is increased in persons with impaired glucose tolerance.[21] Apparently, treating diabetes does not seem to alter the risk for stroke.[94] Thus, it has been concluded that there is no known justification to treat hyperglycemia without evident diabetes if the aim is to reduce the likelihood of stroke.[95] In a study of cases of hyperglycemia with or without diabetes mellitus, the neurologic outcome in stroke was considerably worse, and there was a significantly greater number of stroke-related deaths.[96] In a double-blind, randomized clinical trial, the presence of diabetes mellitus erased the prophylactic effect of aspirin in cases of threatened stroke.[97]

The relationship between *blood lipids* and stroke is weak and uncertain,[95] possibly because patients with higher serum lipid values may not survive to the age at which strokes are common. The Framingham study suggested an association of blood lipid levels with the development of precocious atherosclerotic brain infarction only in men younger than 55.[21] Native Japanese, however, who have a higher stroke mortality than US Japanese, had lower cholesterol levels than Japanese-Americans.[98] Serum cholesterol levels were negatively associated with the risk for intracranial hemorrhage among Hawaiians of Japanese extraction.[31]

In 138 patients who had not suffered a completed stroke but who underwent carotid endarterectomy for extracranial vascular disease, the mean elevation of triglyceride levels was significantly higher than in controls, suggesting that elevated triglycerides rather than cholesterol are a risk factor in extracranial atherosclerotic cerebrovascular disease.[99] Hypertriglyceridemia and elevated pre-β-lipoprotein levels were described in 50 patients with ischemic thrombotic stroke.[100] In men, the presence of elevated serum triglyceride levels doubles the risk for cerebral infarction.[55] Hypertriglyceridemia rather than hypercholesterolemia seems to correlate best with thrombotic stroke occurring before age 50.[100-102] In one study, elevated serum cholesterol values were inversely related to the occurrence of intracranial hemorrhage.[53] Serum triglyceride levels tended to be higher in patients suffering infarction in the distribution of a cortical artery. In them, the ratio of high-density lipoprotein to low-density lipoprotein cholesterol was lower than in patients with strokes traceable

to obstruction of a perforating artery,[103] suggesting that these lipoprotein abnormalities may play a part in the pathogenesis of cerebral cortical infarctions.

Serum *uric acid* elevation has been mentioned as a contributor to the risk for stroke in one study[100] but not in others.[99] Neither persons with gout nor their first-degree relatives were found to have an increased risk for dying of cerebrovascular diseases.[104]

The slight excess in deaths from cerebrovascular diseases reported in smokers of both sexes[105] was verified for men.[55,106-108] Male college students smoking ten or more cigarettes a day were at twice the risk for eventual fatal stroke than those who smoked less or not at all.[42] Although some studies failed to identify a definite relationship between *cigarette smoking* and stroke,[95,105] a relationship probably exists in view of the presence of a dose effect and the reduction in risk that follows cessation of smoking. This emerged from a study of US World War I veterans. Designating 1.0 as the mortality ratio for cerebrovascular diseases among nonsmokers, the following ratios were calculated: current smokers, 1.40; exsmokers, 1.07; pipe and cigar users, 1.06. Among cigarette smokers, a noticeable gradient was associated with increasing daily consumption: fewer than 10 cigarettes, 1.26; 10 to 20 cigarettes, 1.33; 21 to 39 cigarettes, 1.54; two packs a day or more, 1.88.[108] The relationship was stronger in younger age groups and the increased risk associated with smoking appeared to decrease rapidly after cessation.[108]

A collaborative case-control study undertaken in 12 US university hospitals determined that the use of *oral contraceptives* entailed a relative risk of about 9 for thrombotic stroke and of 2 for hemorrhagic stroke.[109] The combined effect of smoking and the use of oral contraceptives selectively increased the risk for subarachnoid hemorrhage.[110] Hypertension compounds the risk for thrombotic stroke among users of oral contraceptives, the relative risk ranging from 3 times baseline value for normotensive users of an oral contraceptive to 14 times in users with severe hypertension.[111]

Alcohol consumption has been positively associated with cerebrovascular diseases,[31,53] the risk increasing with increasing consumption.[112] Acute ethanol intoxication was an immediate antecedent in almost half of 23 consecutive patients younger than 40 years admitted to a Finnish hospital with acute brain infarction.[113] Another Finnish study concluded that a *low level of physical activity* at work was associated with an increased risk for acute myocardial infarction and cerebral stroke in both sexes, even after controlling for age, diastolic pressure, weight and smoking.[114] This observation concurred with the findings of earlier studies of San Francisco longshoremen[115] and of college students[42] indicating that physical activity at work or during leisure time reduced the risk for stroke. Parallel inferences were drawn from a Dutch community-based study that described a dose effect linking inversely the level of physical activity during leisure time with the adjusted relative risk for strokes.[25] The following relative risks were reported: little physical activity, 1.0; light activity, 0.8; heavy physical activity, 0.4. The difference in relative risk between the aggregate of light and heavy physical activity during leisure time and little activity—that is, mainly sitting, was statistically significant.[115]

The literature seems about evenly distributed as to the role of *obesity* in stroke.[25] If anything, the link is weak,[21] as reflected by a relative risk of 1.5[42] to 1.7.[25]

Suboptimal cerebral blood flow, whatever its cause, is potentially harmful in patients at risk for stroke. Thus, under pathologic circumstances, the rheologic properties of blood may become critical,[116] but neither blood viscosity nor the risk for cerebral infarction changes remarkably until the *hematocrit* exceeds 46%, when both increase sharply.[117] The slower flow associated with a higher hematocrit may limit the efficiency of an alternate blood supply through collateral vessels[116] and, distal to a tight stenosis, shear rates may fall and viscosity increase many times. A progressively slower flow will favor thrombus formation.

Fortunately, factors contributing to *hyperviscosity*, such as dehydration, polycythemia and paraproteinemia, can be corrected or at least modified relatively easily. Unfortunately, the same cannot be said about *sickle cell disease*, the cerebrovascular complications of which seem to occur preferentially in children younger than 15 years[118] and where the victim of an initial stroke is more likely to have recurrent cerebrovascular accidents.[118,119] Cerebral infarction in carriers of the sickle cell trait is a rarity[120] and apt to occur only during potentially hypoxic episodes such as status epilepticus or during general anesthesia.

Especially in young adults and adolescents, *drug abuse* is now a significant cause of intracerebral hemorrhage (amphetamines; pentazocine [Talwin] and tripelennamine [Pyribenzamine]; cocaine and phencyclidine); subarachnoid hemorrhage (amphetamines); embolic stroke (pentazocine and tripelennamine, methylphenidate), and ischemic stroke (heroin; pentazocine and tripelennamine; LSD). Direct toxic injury, embolization of foreign matter and pharmacologically mediated vascular change are considered less important etiopathologic pathways than endocarditis and immunologic mechanisms. The latter could explain the frequent polymorphic vascular response and nodose distribution of vascular lesions seen in drug abusers, as well as the delayed onset of stroke after injection or its occurrence after an unusually long period of abstinence.[121] Retrospective observations suggest that in young adults classic *migraine* may be antecedent of stroke.[122]

Primary Sclerosing Cholangitis— An Immunologically Mediated Disease?

R. W. G. CHAPMAN, BSc, MD, MRCP, *and* D. P. JEWELL, DPhil, FRCP, *Headington, Oxford, United Kingdom*

Primary sclerosing cholangitis (PSC) is an uncommon, chronic disorder characterized by inflammatory fibrosis usually involving the entire biliary tree. The etiology has been unknown, but PSC is closely associated with ulcerative colitis, which coexists in more than two thirds of patients with PSC. In recent studies 3% to 5% of all patients with ulcerative colitis had PSC.

We propose that PSC is, at least in part, an immunologically mediated disease; it is closely associated with human leukocyte antigens B8 and DR3, and circulating autoantibodies to colon and portal tract are frequently present. The anticolon antibody cross-reacts with enteric Escherichia coli. *The disease may possibly be triggered in susceptible patients with ulcerative colitis by immunization with antigens shared between enteric microorganisms and the biliary system.*

(Chapman RWG, Jewell DP: Primary sclerosing cholangitis—An immunologically mediated disease? West J Med 1985 Aug; 143:193-195)

Primary sclerosing cholangitis (PSC) is an uncommon disease characterized by chronic inflammatory fibrosis usually affecting the entire biliary tree, causing beading and stricturing of the bile ducts.[1] The clinical syndromes associated with PSC range from the classic cholestatic presentation with jaundice, pruritus, fever and abdominal pain to cirrhosis and portal hypertension without predominant cholestatic features.[2] In addition, an increasing number of patients are being diagnosed by cholangiography at an asymptomatic stage following the discovery of an elevated serum alkaline phosphatase level.[3]

Etiology

Previous Hypotheses

The etiology of PSC is unknown. Since the original description of PSC by Delbet in 1924,[4] a number of possible factors have been suggested as having a role in pathogenesis. PSC is closely associated with ulcerative colitis, which is found in about two thirds of patients who have PSC.[2,5] Consequently, Warren and co-workers[6] suggested that chronic low-grade portal infection, which may occur in some patients with ulcerative colitis, leads to chronic biliary tract inflammation and fibrosis. This explanation seems unlikely, for the extent of hepatic histologic change is unrelated to the incidence of portal bacteremia and there is no direct evidence for a causal relationship between portal bacteremia and the development of PSC.[7-9]

A second hypothesis is that PSC associated with ulcerative colitis is caused by a reaction to toxic circulating bile acids arising from the diseased colon.[10] In three recent studies, however, no major abnormality in bile acid metabolism was found in patients who had PSC or ulcerative colltis (or both).[11-13]

Ludwig and associates have suggested that PSC may be caused by a virus,[8] as cholangitis and biliary atresia may be induced in weanling mice, primates and, possibly, also in infants after infection with reovirus type 3.[14] There is no evidence, however, to support this interesting concept.

The same group has also proposed that the excess liver copper found in PSC patients may have a role in either initiating or perpetuating the disease process.[8] The latter suggestion seems more likely, as excess liver copper is found in patients with chronic cholestasis from any cause.

New Hypothesis

In a number of recent studies it has been suggested that genetic and immunologic factors are important in the pathogenesis of PSC. These suggestions lead us to propose that PSC is, like primary biliary cirrhosis, an immunologically mediated disease,[15] possibly triggered in genetically predis-

ABBREVIATIONS USED IN TEXT
HLA = human leukocyte antigen
PSC = primary sclerosing cholangitis

posed persons by a cross-reaction between antibodies to viral or bacterial antigens in the gut and biliary epithelium.

Evidence

Genetic Factors

In a study of 25 patients with PSC, we found a close association between the human leukocyte antigen (HLA) B8 phenotype and PSC.[16] HLA-B8 was present in 60% of patients with PSC, with and without ulcerative colitis, compared with only 25% of 561 controls. Schrumpf and associates have recently found HLA-B8 in 80% of Scandinavian patients with ulcerative colitis and hepatobiliary disease, most of whom had sclerosing cholangitis.[17] HLA-DR3 was found in 70%.[17] We have confirmed these findings in English patients with ulcerative colitis and PSC.[18] Although the prevalence of HLA-B8 and HLA-DR3 is not increased in a population of patients with ulcerative colitis,[19] it seems that patients with ulcerative colitis unfortunate enough to possess HLA-B8 and HLA-DR3 are at an increased risk for the development of PSC.

Further evidence of the importance of genetic factors comes from Quigley and co-workers who reported the cases of three families in whom ulcerative colitis and PSC developed in two members.[20]

The presence of HLA-B8 and HLA-DR3 has been associated with a number of "organ-specific" autoimmune diseases such as "lupoid" chronic active hepatitis, type I diabetes mellitus, myasthenia gravis and thyrotoxicosis that are associated with the production of autoantibodies.[21] The finding, therefore, of a greatly increased prevalence of HLA-B8 and HLA-DR3 is suggestive that immunologic factors may be involved in the pathogenesis of PSC. This suggestion has been strengthened by a number of recent studies that have shown humoral and cellular immune abnormalities in PSC.

Humoral Immune Abnormalities

Like primary biliary cirrhosis,[15] a disease with which it shares many features, symptomatic primary sclerosing cholangitis is characterized by hypergammaglobulinemia, often with a disproportionate elevation of serum IgM levels.[2]

Although characteristically absent, smooth muscle antibody and antinuclear factor are found in some patients with PSC.[2] These antibodies are usually present only in a low titer and may simply represent a nonspecific result of parenchymal liver damage. We have recently shown, however, that at least two other specific serum autoantibodies are present in PSC patients with ulcerative colitis.[22,23] In our studies 62.5% of patients with ulcerative colitis and PSC have circulating anticolon antibodies compared with only 17% of patients with ulcerative colitis alone.[22] The anticolon antibody did not cross-react with human liver and was not associated with the presence of the HLA-B8 phenotype.[22] We were also able to demonstrate a separate antibody to portal tracts, probably to proliferating bile ductules, from human obstructed liver in the serum of 53% of patients with PSC and ulcerative colitis.[23] This antibody was present in only one patient with ulcerative colitis alone and, interestingly, was closely associated with the HLA-B8 phenotype.[23] The antibody was not found in the serum specimens of 20 patients with extrahepatic bile duct obstruction or 20 with primary biliary cirrhosis. Studies in organ-specific autoimmune disease such as type I diabetes mellitus and pernicious anemia have shown a correlation between serum cytotoxic activity and surface-reactive but not cytoplasmic autoantibodies.[24,25] Further studies are needed in PSC patients to determine whether the portal tract antibody is cytoplasmic, cytotoxic or both.

Additional evidence for the importance of humoral mechanisms in the development of PSC comes from a study by Bodenheimer and colleagues.[26] These workers found elevated circulating immune-complexlike material by at least one method (of two used in the study) in 16 of 20 patients who had PSC with and without ulcerative colitis compared with controls with and without colitis. Immune complexes have also been found in the bile of PSC patients.[27] However, elevated levels of serum immune complexes are not specific for PSC and are found in cases of various liver diseases.[26] Further studies are needed to characterize the nature of the antigen and antibody components of the complexes, which may simply represent an epiphenomenon. It is possible, however, that antibodies against hepatobiliary antigens, such as we have recently described, may form immune complexes in the liver, which play a direct role in tissue injury.

Cellular Immune Abnormalities

Few studies of the cellular immune system have been carried out in PSC. McFarlane and associates found an inhibition of leucocyte migration in response to biliary antigens in patients with PSC, suggesting that their lymphocytes may react with specific antigens in biliary epithelial cells.[28] Similar changes were observed in cases of primary biliary cirrhosis and chronic active hepatitis but not in other forms of cholestatic liver disease.

Schrumpf and co-workers studied T-cell subsets in 11 patients with ulcerative colitis and PSC.[17] They could not find any abnormality in total T-cell numbers or in the ratio of helper to suppressor cells, compared with normal controls.[17]

It is likely, however, that there will be some abnormality in T-cell function in patients with PSC. It has been shown in patients with dermatitis herpetiformis and in normal controls that the HLA-B8 and -DR3 antigens are associated with a low number of Fc-receptor-bearing T cells and a functionally defective Fc-receptor function.[29]

Relationship With Ulcerative Colitis

On the evidence presented it seems likely that PSC is an immunologically mediated disease. How then to explain the close association with ulcerative colitis?

It has been suggested that immunologically mediated diseases are the result of an interplay between independent, antigen-nonspecific defects and antigen-specific defects.[15] The HLA-B8- and HLA-DR3-linked gene is in some way responsible for an antigen-nonspecific increase in immune responsiveness[21] and the disease specificity in PSC must reside in some other non-HLA-linked, genetic or environmental influence somehow linked to ulcerative colitis. The situation may be analogous to the association of ankylosing spondylitis with ulcerative colitis. Although the prevalence of HLA-B27 is not increased in ulcerative colitis, in patients with ulcerative co-

litis and HLA-B27 there is a higher risk for ankylosing spondylitis developing than in controls.[30] There is evidence of antigenic cross-reactivity between HLA-B27-positive lymphocytes and antigens present on *Klebsiella pneumoniae*.[31] It is postulated that this may result in disease by either the production of microbial antibodies that also have an "antiself" activity or that *Klebsiella* antigens may bind to the HLA complex, rendering it susceptible to immune attack.[30] As previously discussed, approximately one fifth of patients with ulcerative colitis have circulating anticolon antibodies, which are not seen in normal controls.[22] The colonic antigen is probably a mucopolysaccharide located in the cytoplasm.[32] It shares determinants with a heterogenetic antigen that is a constituent of most Enterobacteriaceae strains,[33] including *Escherichia coli* O14, which has been shown to cross-react with the colon antigen.[34] The significance of anticolon antibodies in the pathogenesis of ulcerative colitis is unclear, as they are not directly cytotoxic to human colonic cells in tissue culture.[35] They may act, however, by invoking antibody-dependent cell-mediated cytotoxicity against colonic epithelium in cases of ulcerative colitis.[36] The distinct portal tract antibody in PSC may also represent a cross-reacting antibody to an enteric microorganism. This antibody, in genetically predisposed patients with and without ulcerative colitis with HLA-B8, HLA-DR3 and heightened immune responses, could also play a role in the development of PSC through the variety of direct or indirect immunologic mechanisms already discussed.

Implications for Therapy

Symptomatic PSC is a severe, debilitating disease usually culminating in death from progressive liver failure or bile duct carcinoma.[2,5] Current medical therapy is unsatisfactory.[9] If our hypothesis is correct, then immunosuppressive agents such as corticosteroids or cyclosporine administered either singly or in combination may be beneficial at an early stage. We and others have stated that corticosteroids should not be used in cases of long-standing PSC because of the hazards of corticosteroids accentuating osteoporosis in patients with cholestasis.[2,5,9] There has been no controlled trial, however, and it is possible that patients with early disease may benefit from a regimen of corticosteroids.[37] Cyclosporine is a new immunosuppressive agent that may prove to be of benefit in PSC, although in view of its numerous side effects it should be studied only in a carefully controlled and monitored clinical trial.

Drownings of Children and Youth in a Desert State

SALLY DAVIS, MEd; JUDY LEDMAN, MD, *and* JULIE KILGORE, *Albuquerque*

Despite the fact that New Mexico is a desert state, the drowning rate (4.3) is 40% higher than that nationally (3.0). More than half of those who drown are younger than 25 years, toddlers and adolescents being at greater risk than other age groups. In an epidemiologic study of a six-year period, male drowning victims outnumbered female and American Indian and Hispanic victims outnumbered whites. Other major risk factors were epilepsy, mental retardation and alcohol abuse. In most drownings in the under-25 age group, the victim was involved in recreation near the water or swimming, although many were partially or fully clothed. Most drownings occurred in lakes, ditches or rivers. Because New Mexico is not a water-oriented state, public awareness of drowning hazards needs to be increased and more intensive preventive efforts instituted.

(Davis S, Ledman J, Kilgore J: Drownings of children and youth in a desert state. West J Med 1985 Aug; 143:196-201)

Drowning is a common cause of death in children and youth throughout the world.[1] In the United States it is second only to vehicle accidents as the most common cause of accidental death in persons younger than 25.[2] Most studies of drownings have looked at densely populated, water-oriented regions,[3-8] with the assumption that drowning is not as serious a problem in areas where fewer people participate in water sports and activities. The results of our study show that this assumption may be false.

Unlike Maryland,[8] Florida,[3] Hawaii[4] and Australia,[5-7] neither climate nor geography in New Mexico encourages water sports. This sparsely populated, rural state is arid and mountainous with few lakes and rivers. Irrigation by canals and ditches is common, however, and this water source has been thought to pose a significant threat to children. There have been no water-related catastrophes—that is, accidents in which five or more persons are killed[9]—in recent years, but spring thaw often creates flooding in places that are dry during the rest of the year.

This description of the state would suggest that mortality due to drowning should not be a major problem. However, New Mexico, with a population of 1,122,500 in 1975, had a drowning rate (deaths per year per 100,000 population) of 3.5 compared with the national rate for the same year of 2.5.[10] A systematic study was done to determine the specific patterns of drownings.

Methods

A list of all drownings of persons between 0 and 24 years of age for the years 1975 through 1980 inclusive was selected from records of the New Mexico State Office of the Medical Investigator, the central depository for all records of accidental death. This list was compared with the records of drowning from the New Mexico Health and Environment Department Vital Statistics Bureau. In a few cases, because the two listings were not identical, additional cases were added.

Each original case file was reviewed for pertinent information from the investigator's report and, when available, the autopsy and toxicologic and police reports. Records varied in completeness. Information such as activity before drowning, the body of water, supervision, alcohol consumption and ability to swim was incomplete in some cases.

Information on age, sex and county of death was available in all cases. Ethnicity was specified for American Indians and blacks, but Anglo* and Hispanic were usually grouped together as whites. Hispanic ethnicity was assigned according to the *1980 Census List of Spanish Surnames.*[11] Denominators were obtained using 1980 census figures by individual year of age, sex and ethnic groups.[12,13] Estimates for mid-1977 were obtained by "younging" the population. A detailed explanation of the denominator calculations may be obtained on request from the New Mexico Tumor Registry, 900 Camino de Salud NE, Albuquerque, NM 87131.

Results

Age, Sex and Ethnicity

A total of 329 drownings was reported in New Mexico

*Anglo designates a white inhabitant of the United States of non-Hispanic origin.

From the Department of Pediatrics, University of New Mexico School of Medicine, Albuquerque. Ms Kilgore is now affiliated with the University of New Mexico College of Education.

Submitted, revised, October 29, 1984.

Reprint requests to Ms Sally Davis, Dept of Pediatrics, Surge Bldg, University of New Mexico School of Medicine, Albuquerque, NM 87131.

TABLE 1.—*Number of Drownings in New Mexico by Age, Sex and Ethnic Group, 1975 Through 1980*

Age Years	Males					Females					Total
	Anglo	Hispanic	American Indian	Black	All Males	Anglo	Hispanic	American Indian	Black	All Females	
0-4	18	11	4	0	33	12	6	2	0	20	53
5-9	2	4	3	0	9	2	2	0	1	5	14
10-14	6	9	2	2	19	1	7	0	0	8	27
15-19	12	20	12	1	45	1	3	1	0	5	50
20-24	16	18	6	0	40	2	3	2	0	7	47
Total	54	62	27	3	146	18	21	5	1	45	191

All ages = 329

over a six-year period, 1975 through 1980 inclusive. More than half of the deaths, 191 (58%), were of persons younger than 25 years. The highest rate of drowning (8.2 per 100,000 annually) occurred in the 0 to 4 years age group, closely followed by those in the 20 to 24 (6.5) and 15 to 19 (6.4) years age groups. The total number of drownings by sex, age and ethnicity for the six-year period are shown in Table 1.

A disproportionate 76% of the drownings of persons younger than 24 years involved male victims. As both Table 1 and Figure 1 show, male victims outnumbered female victims for all ages.

Rates by sex and ethnicity are given in Figure 2. The highest rates are those for male victims in the following order: American Indians (14.9), Hispanics (8.4) and Anglos (6.5).

Location and Activity Before Drowning

Figure 3 gives the frequency by body of water in which a drowning occurred and by the activity of the victim before the drowning. In New Mexico, most drownings (71%) occurred in lakes, ditches or rivers.

Immediately before their deaths, 74 of the victims were playing, fishing, picnicking or involved in other recreation near but not in the water. Another 55 were reported to be swimming. Many of these victims were found fully or partially dressed, indicating that swimming may not have been a planned activity. Swimming was the most frequent activity before the accident only for lake, pool and pond drownings. In river and ditch drownings, most victims were involved in activities near but not in the water.

There were seven multiple drownings. In each of six cases, two persons died and, in another, three adolescent girls drowned after they fell from a dam into a river and were washed through flood gates. Of the two-person drownings, two involved scuba divers, two were related to acute alcohol abuse and two were rescue attempts.

In addition to the two multiple drownings, there were three single drownings during rescue attempts. There were also several cases in which a rescue was attempted, and the victim, in his or her panic, endangered the rescuer and caused the attempt to be abandoned.

Predisposing Factors

In some drownings important predisposing factors were present and may have contributed to the drowning. For example, 12 victims had a history of seizures or mental retardation (or both), which may have compromised their ability to protect themselves in water. The most common factor that may have compromised victims was the use of alcohol. It was difficult to determine the exact prevalence of alcohol use in association with drowning because blood alcohol determinations were not done routinely. For the most part, blood alcohol concentrations seemed to have been measured when the circumstances surrounding the drowning were suggestive of

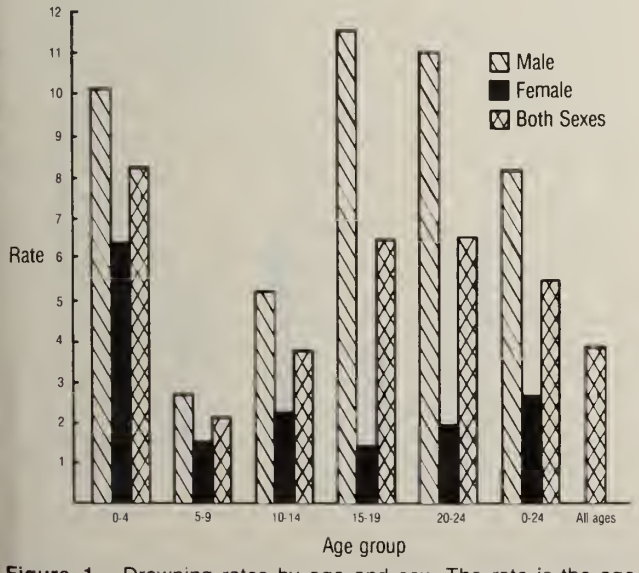

Figure 1.—Drowning rates by age and sex. The rate is the age-adjusted rate per year per 100,000 based on the 1977.5 adjusted census.

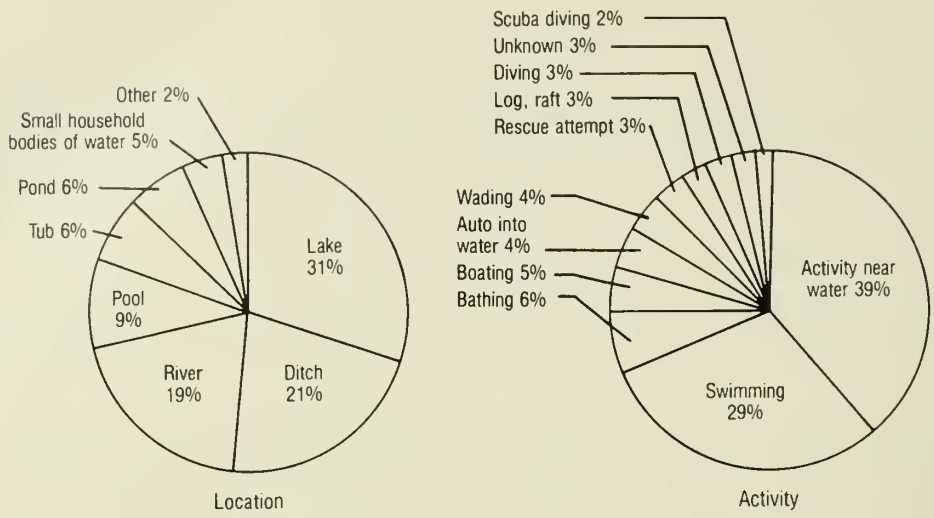

Figure 3.—Frequency of drowning by activity and location.

alcohol use. In several cases in which alcohol determinations were not made, however, eyewitness reports that the victim had been drinking were present in the file. Because all those drownings in which an alcohol level was not determined were assumed not to be alcohol related, the prevalence of alcohol use in relationship to drownings is thought to be underreported.

Of the 191 victims listed by the Office of the Medical Investigator, 90 had alcohol determinations. Of the 43 who had evidence of alcohol use, 25 had an alcohol concentration of greater than 0.1 mg per dl and 18 had a value of 0.01 to 0.1 mg per dl. These 43 cases are classified as alcohol-related drownings. They were compared with those in which alcohol concentrations were not determined plus those in which alcohol determinations gave negative results.

All alcohol-related drownings occurred in persons 15 years or older: 20 were in the 15 to 19 years age range and 23 were in the 20 to 24 years age range. In the 15 to 24 years age group, 44% of all drownings were alcohol related. Only four of the alcohol-related drownings involved female victims.

Rescue and Resuscitation

Of the 91 drownings, resuscitation attempts were recorded in 46 (24%). Six victims were still being resuscitated when they reached the hospital. Five lived from a few minutes to a few days, and one person survived in a coma for 4½ months. It is noteworthy that 13 of the 46 resuscitation attempts occurred at swimming pools. This represents 13 of 18 of the pool drownings. Only 9 of 97 drownings in lakes, reservoirs and rivers resulted in resuscitation attempts. In 4 of 9 bathtub drownings, 3 other home drownings, 1 car submersion and 15 other drownings in small bodies of water, resuscitation was attempted. No data on successful resuscitations were available.

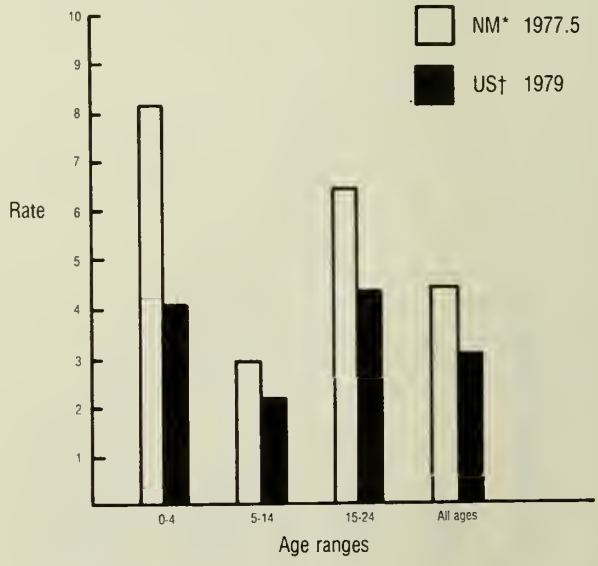
Discussion

There may be a false assumption that drowning is a problem only in water-oriented regions. The New Mexico drowning rate for all ages was 4.3, calculated for the midpoint between 1975 and 1980, whereas the rate for the whole United States was 3.0 for 1979.[2] Figure 4 shows that drowning rates in New Mexico were higher than national figures for toddlers, children and adolescents/young adults as well.

Other states that report a high incidence of drowning such as Florida,[3] Hawaii[4] and Maryland[8] are characterized by the universal presence of bodies of water and may have climates that allow water-related activities to be pursued year round. In contrast, the climate of most of New Mexico is warm only in the summer and there are fewer than 20 lakes with state recreational facilities in a state of more than 77,866,240 acres.[14] Because this is not an environment that fosters water sports to any major degree, other factors contributing to the substantial loss of life due to drowning should be considered.

Human Factors

Sex, age and ethnicity. We found that the distribution of drownings by sex and age was similar to that in other studies and that reported in national and international statis-



*Age-adjusted rate per year per 100,000 based on the 1977.5 adjusted census.
†Figures from National Safety Council.[2]

Figure 4.—Comparison of drowning rates for New Mexico and for the United States.

tics.[1-5,7,8,15-17] Drowning victims of all ages are more likely to be male than female.[3-5,15-17] This may be due to the greater level of exploration and risk taking exhibited by and encouraged in men and boys. In addition, male children may be less closely supervised than female children.[17] Another familiar pattern is the age distribution of the victims. Toddlers[1,2,4,7,15] and adolescents[2,8,15] are at greater risk than children in other age groups.

A third human factor in the New Mexico study was ethnicity. Although no other studies have specifically looked at drowning rates of Hispanics and American Indians, it is known that the overall accident rate for these groups is high.[18-21] Other studies have shown similar high rates for minority populations.[3,8] Socioeconomic and cultural factors obviously play an important role in the cause of accidents such as drowning.

Activity before drowning. Another important human factor is the activity of the victim before drowning. Nationwide, swimming and playing near water are the activities that pose the greatest threats for children and young people aged 0 to 24 years.[15-22] Of the two activities, the New Mexico study found recreation near the water (39%) more common before drowning than swimming (29%).

One study reports that nationally water sports other than swimming (including boating, rafting, skin and scuba diving) accounted for 13% of 3,303 drownings in the 0 to 24 years age group. In all, 7% of the total drownings in this age group were boating accidents.[15] In New Mexico 13% of the drownings in the 0 to 24 years age group were also attributed to water activities other than swimming or wading. Only 10 (5%) were accidents involving boats. One victim was a 3-year-old girl who disappeared from a houseboat. The other nine were all males and ranged in age from 12 to 24 years. Seven were fishing or boating in small boats on lakes or rivers when the boat was overturned or they fell into the water. Five of the seven either were reportedly drinking or had significant blood alcohol concentrations. None wore life jackets. Five other deaths occurred after falling from a raft, kayak or canoe. One of these five victims had a significant alcohol level. One, who was kayaking in river rapids, wore a life jacket. In addition, a 13-year-old boy on an inner tube and another 13-year-old boy on a log were nonswimmers who slipped from their makeshift device into the water and drowned. Four deaths (involving two pairs of divers) were reported among scuba divers. There were no deaths of water skiers. Most of these drownings are characterized by preventable human factors.

Multiple drownings and rescue attempts. Many drowning accidents are prevented by other people who are present and can assist the victim. However, occasionally multiple drownings occur either because neither person can handle the water conditions or because a person attempting rescue is lured into a dangerous situation. The *Statistical Bulletin of the Metropolitan Insurance Companies* reported 143/4,962 (3%) drowning deaths occurred during rescue attempts.[15] In the five-state study reported by Press and co-workers, 42/1,024 (4%) drownings occurred in persons who were trying to save someone else.[22] In the New Mexico data, 5/191 (3%) of the deaths were clearly associated with rescues. Rescue attempts, though not recorded as such, could have been a factor in several other multiple drownings.

There is little information on multiple drownings other than the association with rescue attempts. In one study multiple drownings were reported in skin and scuba divers but the occurrence was in only 5% of the total diver drownings.[23]

Predisposing factors. We and others[8,24,25] have identified a small group of victims with disabling conditions that may have contributed to their drowning. In our study, 12 victims had predisposing disabling factors other than alcohol consumption. Eleven had a seizure history, mental retardation or both. Five of these died in bathtubs. Another victim had a history of drug abuse and had head trauma a week before the accident.

Alcohol use is a known risk factor for injuries.[26,27] Several previous studies have specifically linked alcohol use with drowning.[8,28-30] Mackie[31] reviewed this literature and reported the alcohol-related drowning incidence to be from 14% to 79% of all drownings for various populations.

It is not surprising to find alcohol as a major risk factor in drownings in New Mexico. A recent study by the National Institute of Alcohol Abuse and Alcoholism found New Mexico to lead the country in the number of chronic health problems and number of casualties attributed to alcohol abuse.[32] Our study confirms a high incidence of alcohol-related drownings (44%) in the 14 to 24 years age group. Male victims predominate and there are differences in the incidence of alcohol-related drownings by ethnicity for both sexes.

In general, a high alcohol abuse rate in New Mexico adolescent and young adult populations appears to be a major factor for the excessive drowning rate in the state.

Environmental Factors

Lakes, rivers and ditches. As expected, the incidence of drowning by body of water varies widely depending on the availability of water sources in different areas.[22] In data compiled for all ages from the whole United States, most drownings occurred in lakes (23%), rivers (22%), swimming pools (13%) and salt water sources (9%).[33] In Florida most drownings occur in swimming pools followed by canals and then lakes or ponds,[3] whereas in Maryland drownings are most frequent in rivers, then lakes and then salt water sites.[8] In Honolulu the rank order of drowning sites is swimming pools, salt water sources and domestic bathtubs.[4]

The New Mexico data reflect the pattern of water site availability unique to this area. In the 0 to 24 years age range, most drownings occurred in lakes (31%), followed by irrigation ditches and canals (21%) and then rivers (19%). However, the age of the victim is an important factor in evaluating location of drowning. In the adolescent and young adult groups, 44% and 47%, respectively, died in lakes and 18% and 28% in rivers. In contrast, toddlers were most likely to drown in ditches (38%) or small bodies of water in or around the home (17%) and relatively few died in lakes (9%) or rivers (11%).

Swimming pools. Nationally, swimming pool drownings have increased in recent years, with more pool drownings occurring in Arizona, California, Hawaii and Nevada than in other areas of the country.[34] In New Mexico only 9% of the drownings occur in swimming pools. This is not surprising since there are few private or public pools in the state due to economics and the climate factors mentioned earlier.

Bathtub drownings and other household water sources. Bathtubs have previously been identified as an important site of infant drowning. Unlike other childhood accidents that show a male predominance, the sexes are equally affected in this case. Although most of these incidents involve infants, there is an occasional report of bathtub drowning in older persons with certain predisposing factors.[7,35,36]

In our study, 11 bathtub drownings fell into two categories. Five children younger than 25 months drowned after being left unattended in a bathtub. Six older children or young adults with predisposing disabling conditions such as seizures or mental retardation died in tubs. All but one of the bathtub drowning victims were female.

Nine other unattended toddlers died in small household bodies of water such as cesspools and stock troughs. Two of these children died in buckets containing only a few inches of water. Pail-immersion accidents have been reported by previous investigators[37-40] as well.

Rescue and resuscitation. The environment affects chances of rescue and resuscitation. Many of the drownings occurred in unsupervised bodies of water characterized by dangerous, steep and muddy banks; swift currents; cold temperatures; drop-offs, and murky water filled with debris—all factors making swimming unsafe and prompt rescue difficult or impossible.

If a victim was recovered quickly or if time submerged was unknown, resuscitation was usually begun at the scene and continued in transport by emergency personnel. The resuscitation attempt rate (24%) was low, reflecting the many victims who were not recovered immediately.

Of the 18 persons who died in swimming pools, 13 (72%) resuscitation attempts were recorded. Lifeguards were involved at only three sites, however. In addition, it is known that resuscitation was attempted in 5 of 11 bathtub drownings and in 3 other home drownings. In one case two persons drowned after their car left the road and plunged into water. They were easily found and resuscitation was attempted. Fifteen others who received resuscitation drowned in smaller bodies of water such as ditches, ponds or stock tanks. Thus, only 9 of the 46 victims in whom resuscitation was attempted were recovered from large bodies of water such as lakes, reservoirs and rivers. The resuscitation attempt rate at these sites was 9 in 97 (10%). As expected, the chance of a resuscitation attempt varied with the drowning site and seemed to be related to rapidity with which the victim could be found and recovered.

Summary

Distribution of immersion accidents by body of water in New Mexico varies from that described in different geographic areas.[3-5,8,22] The greatest number occurred in lakes, ditches and rivers. Almost as many drownings happened in bathtubs, ponds and small household bodies of water as occurred in swimming pools, each accounting for less than 10% of the total. Recreation near water and swimming were the most common activities before drowning. It is of interest to note, however, that victims were often fully or partially clothed, in some cases even wearing boots. This suggests that swimming may have been a spontaneous rather than a planned activity. In most cases, the location of drowning was not a supervised recreational area. The population is generally unaware of possible hazards and uneducated regarding aquatic sports and safety. It is ironic that New Mexico's lack of water may actually contribute to the high incidence of drownings.

While the distribution of drownings by body of water may be geographically specific,[22] the population groups at risk appear to be universal. Males,[1,3-5,15-17] toddlers,[1,2,4,7,15] adolescents[2,8,15] and minorities[3,8] appear more likely to drown no matter where the accident occurs. Similar factors predisposing to drowning such as epilepsy,[8,24,25] mental retardation[23,24] or alcohol abuse[8,26-31] have been reported in other studies.

Of the many factors that contribute to the cause of drowning, the role of human behavior appears most prominent. Socioeconomic and cultural factors reflected in the differences in death rates by ethnicity must also be taken into consideration. While it is not likely that a drowning prevention program could make many changes in social, political and economic environments, it is conceivable that changes can be made in human behavior and to some extent the physical environment. Efforts should be concentrated in these areas.

The first step should be a statewide media campaign to elevate public awareness regarding the hazards associated with drownings and the particular vulnerability of specific population groups. Particularly dangerous locations need to be publicized. Needed behavioral and environmental changes should be identified and preventive efforts in that direction reinforced. Committing public funds for barrier construction, supervised swimming areas, aquatic education and cardiopulmonary resuscitation should be encouraged. Coordinated efforts of public health, education, community recreation groups and the Red Cross should be visibly supported by publicly documenting their efforts.

Aquatic education should be included in every school program. Communities should join with the schools in combined recreational efforts that teach swimming, water safety and cardiopulmonary resuscitation. In one isolated rural area, children are bused during the summer to a larger community with a pool where they receive instruction in swimming and water safety. Similar efforts should be made in other areas where established programs are not available. Safety instruction should include the dangers of combining alcohol use and swimming and the hazards of swimming in unsupervised bodies of water. Physicians should not overlook the importance of one-to-one safety counseling. Persons should at least have adequate and accurate information with which to make informed decisions.

Drowning epidemiology should be examined by desert states as well as those states that encourage water activities. Data from such epidemiologic studies will focus preventive efforts in the appropriate direction. Without such studies we may overlook important causal factors and misdirect our efforts.

Blood and Plasma Substitutes—Plasma Expansion and Oxygen Transport Properties

KENNETH WAXMAN, MD; KEVIN K. TREMPER, PhD, MD, *and*
G. ROBERT MASON, MD, PhD, *Orange, California*

Because of the risks and costs of blood and blood product infusion, developing blood and plasma substitutes is of significance. Two currently utilized substances, dextran and hydroxyethyl starch, are effective colloid plasma expanders. The dextrans have properties that improve microcirculatory blood flow but are associated with several possible adverse effects. Hydroxyethyl starch is a well-tolerated agent that has efficacy similar to albumin but at a lower cost. Two newer substances, perfluorocarbons and stroma-free hemoglobin, are being developed to improve oxygen transport as well as plasma expansion.

(Waxman K, Tremper KK, Mason GR: Blood and plasma substitutes—Plasma expansion and oxygen transport properties [Medical Progress]. West J Med 1985 Aug; 143:202-206)

There are increasingly important limitations to the use of blood and plasma in treating cases of hypovolemic shock. Blood and blood products have limited availability, there is increasing concern over infectious and immunologic risks and the costs involved in obtaining, storing, cross matching, processing and dispersing blood and blood products continue to rise. There is, therefore, a clear role for effective blood and plasma substitutes. Not only do these solutions provide a cost-effective alternative to blood products, they also allow conservation of this limited resource for those patients who most need it.

Electrolyte solutions containing sodium (crystalloids) have been shown to be effective but relatively inefficient plasma volume expanders. They are inefficient because, once infused intravascularly, they distribute over the entire extracellular fluid space, only a relatively small portion of which is the plasma volume. Large volumes of crystalloid fluids, therefore, need to be infused to result in effective plasma volume expansion. Colloid fluids contain larger molecules that diffuse relatively slowly across the semipermeable capillary membranes. These fluids are, thus, effective plasma expanders. Following Starling's concepts in 1896 of colloid osmotic pressure as a regulator of the plasma volume, interest arose in developing colloid plasma expanders. The first colloid plasma substitutes were tested around the turn of this century, when gum acacia was used as a volume expander. This substance is a carbohydrate exudate from *Acacia* trees and was used clinically during World War I. It proved to be highly antigenic, however, and anaphylaxis was common following its infusion.[1] Gelatin solutions derived from collagen were also developed in the early 1900s and these too were used clinically during World War I. Gelatin solutions of 3% to 4% are still used clinically in Europe, but have not been used in recent years in the United States for several reasons. The plasma expansion following gelatin infusion is short lived because of rapid urinary excretion. Further, gelatin infusions are antigenic and anaphylaxis may occur, particularly with repeated infusions.[2,3]

In this review we discuss four examples of modern plasma substitutes, the dextrans, hydroxyethyl starch, perfluorochemical emulsions and stroma-free hemoglobin. Each of these is a colloid fluid with the potential for efficient plasma volume expansion. Stroma-free hemoglobin solutions and perfluorochemical emulsions not only expand plasma volume but can transport additional oxygen as well.

Dextran

In 1944 the dextrans were introduced in Scandinavia as plasma volume expanders. Dextrans are polysaccharides produced by the conversion of sucrose into long glucose polymers by the bacterial enzyme dextransucrase. Clinically used dextrans are produced by a specially developed strain of bacterium, *Leuconostoc mesenteroides*. The molecules produced by the bacteria are very large, with molecular weights of several millions. For intravenous infusion, partial acid hydrolysis produces dextran fractions of specified weight ranges. Two dextran solutions are now most widely used, a 6% solution with an average molecular weight of 70,000 (dextran 70) and a 10% solution with an average weight of 40,000 (dextran 40, low-molecular-weight dextran). These

ABBREVIATIONS USED IN TEXT

2,3-DPG = 2,3-diphosphoglycerate
HES = hydroxyethyl starch
P-50 = oxygen half-saturation pressure of hemoglobin
Pao_2 = partial arterial oxygen pressure (tension)
PFC = perfluorochemical

molecular weights are averages as dextran solutions, in fact, contain a range of various-sized dextran molecules. The dextrans can be efficiently produced in large quantities and stored for many years at room temperature either in powdered form or in solution.

Dextran is mainly excreted unchanged in the urine. The rate of renal excretion depends on molecular size, with smaller dextran molecules being excreted rapidly and larger molecules (above 50,000 molecular weight) excreted very slowly. Dextran molecules not excreted in the urine slowly diffuse into the interstitium where uptake into the reticuloendothelial cells and slow metabolism to carbon dioxide occur.[4] Reticuloendothelial cell dysfunction as a result of this uptake has been postulated, but the clinical implication of this remains unproved.

The plasma half-life of dextran solutions depends on their molecular size (dextran 40 being excreted more rapidly than dextran 70), but dextran 40 solutions have a higher oncotic effect per gram infused and, thus, produce a more pronounced, if more short-lived, plasma volume expansion.[5]

In addition to plasma volume expansion, dextran solutions have several physiologic effects that have clinical import. Dextran solutions have antithrombotic effects, probably mediated by inhibition of platelet aggregation in addition to augmentation of microcirculatory blood flow.[6-8] One of the most important implications of dextran administration to patients in shock is its effect on microcirculatory blood flow. A major pathophysiologic deficit following shock is decreased microcirculatory blood flow, which impairs oxygen transport to the tissues. Administering dextrans, particularly the low-molecular-weight dextrans, may greatly improve microcirculatory flow. This effect is mediated by two mechanisms: (1) the viscosity of blood is decreased by hemodilution, as with any effective volume expander; (2) low-molecular-weight dextrans specifically inhibit erythrocytic aggregation and, thus, reverse and prevent erythrocytic sludging.[4,9]

Anaphylactic reactions to dextran are unusual, occurring in 0.03% to 0.07% of patients, but may be severe and even fatal. When reactions occur, they do so usually during infusion of the first 100 ml. Patients may have severe anaphylactoid reactions even with no previous exposure to dextran given intravenously.[10] Close clinical observation of patients during the initiation of dextran infusion is mandatory.

Dextran, as previously discussed, affects normal coagulation. This effect is dose related—that is, low doses of dextran (less than 1.5 grams per kg of body weight) are not associated with clinical bleeding, but platelet adhesiveness is decreased, and plasma levels of clotting factors are also decreased.[5] Larger doses of dextran have been associated with significant bleeding complications.[11] Precipitation of acute renal failure has been thought to follow infusion of dextran, although this is controversial.[5,12,13] Low-molecular-weight dextran has been particularly implicated. A possible mechanism for this is the accumulation of the dextran molecules in the renal tubules, causing tubular plugging. Renal failure following dextran use is more often reported when renal perfusion is reduced or when preexisting renal damage is present.

Another problem that has been reported with dextran infusion is the subsequent difficulty in cross matching blood for transfusion.[14] This effect may be mediated by the adherence of the dextrans to antigens on the red cell membrane. In practice, this problem can be circumvented by obtaining a blood specimen for cross matching before infusion.

Dextran was initially used clinically during the Korean War. Since that time there have been numerous experiences with more than 60 million units of dextran infused into patients.[5] Problems have been delineated, particularly the risk of increased bleeding and anaphylaxis. The current uses of dextrans as plasma expanders fall into several categories.

Dextrans are effective plasma volume expanders with efficacy equal to or superior to albumin. A number of studies have shown this plasma volume expansion, with subsequent hemodynamic improvement.[5,15-18] A practical restriction of dextran in this regard, however, is its effect on clotting, necessitating dose limitation in bleeding and perioperative patients to 1,000 to 1,500 ml per 24 hours. Furthermore, the possibility of precipitating acute renal failure has limited its use in oliguric patients. Finally, the possible impairment of blood cross matching must be considered in this setting.

Low-molecular-weight dextran has also been used effectively as a plasma substitute for priming in extracorporeal circulation. In some studies it has been found to have advantages over other colloid solutions for this purpose, in decreasing erythrocyte and platelet destruction.[19,20]

The improved microcirculation following low-molecular-weight dextran infusion may offer therapeutic advantage in reversing erythrocytic sludging following severe trauma, shock and sepsis.[5,9,15,21,22] Dextrans have also been studied and used as possible effective modalities in treating patients with myocardial ischemia, cerebral ischemia and peripheral vascular disease and in maintaining vascular graft patency.

Hydroxyethyl Starch

Starch is the energy storage polysaccharide of plants and is analogous functionally and structurally to glycogen, the energy storage polysaccharide molecule of animals. Starch is composed of two types of glucose polymers: amylose, a linear molecule, and amylopectin, a highly branched molecule that structurally resembles glycogen. Amylopectin is well tolerated when infused intravascularly into animals, but is rapidly hydrolyzed enzymatically (amylase hydrolysis), with a half-life of only about 20 minutes. In the early 1960s, work by Thompson and others showed that modification of the amylopectin molecule would make it more stable within the plasma.[23] This was successfully accomplished by substituting hydroxyethyl groups to create hydroxyethyl starch (HES).

Commercially available HES solutions contain a heterogeneous solution of HES molecules, with an average molecular weight of 69,000, similar to albumin. The range of molecular size, however, is from 10,000 to 100,000. This has implications when considering elimination of HES from the vascular space. Smaller molecules are excreted unchanged into the urine, whereas larger molecules slowly diffuse into the interstitium where slow enzymatic degradation occurs. In normal subjects, HES is nearly completely cleared from the

plasma within two days (half-life is 17 hours), yet only about 50% of the HES is eliminated from the body. The remaining HES is eliminated very slowly and much of the initial dose persists for weeks after infusion, some of the larger HES molecules probably accumulating in the reticuloendothelial cells.[24]

Hydroxyethyl starch appears to be an extremely well-tolerated plasma expander, with adverse effects infrequent and relatively mild. Allergic reactions to HES are distinctly uncommon; unlike dextran, HES is not antigenic.[23] In one large study, the incidence of allergic reactions to HES was 0.085% compared with 0.011% for albumin infusion.[25] In this large study there were no fatal anaphylactic reactions to HES.

The only clinically important adverse effect of HES infusion appears to be some impairment of coagulation. This effect seems to be dose related. Low doses have no effect on coagulation, whereas moderate doses (20 ml per kg) have the following effects: platelet counts may transiently decrease or remain normal; platelet function, including platelet adhesiveness, remains intact and bleeding times remain normal; prothrombin time and partial thromboplastin time may be prolonged, and fibrinogen levels may decrease.[23,26,27] Although these effects may be measured, there is no evidence of clinical bleeding problems with HES infusions of as much as 20 ml per kg.[28] There have been no controlled human studies of larger infusions with HES, but studies of animals have shown increased incisional bleeding, increased intraoperative blood loss and spontaneous serosal bleeding when very large doses of HES are infused.[11]

A problem of unclear significance with HES infusion is an occasional elevation of the serum amylase level. Whether this hyperamylasemia is the result of subclinical pancreatitis, whether HES acts as a physiologic stimulant to pancreatic amylase secretion or whether it is the result of amylase aggregation is unknown.[29] The only important clinical implication appears to be that HES infusion in patients with pancreatitis might compromise the interpretation of serum amylase values. Unlike dextrans, HES does not interfere with the typing or cross matching of blood, and there appears to be no adverse effect on renal function.[23]

Hydroxyethyl starch has been well studied for its efficacy as a plasma volume expander. HES (6% solution in saline) increases plasma volume from 71% to 230% of the volume infused.[30-34] The colloid osmotic pressure is increased significantly following HES infusion, and this explains the ability of HES to expand the plasma volume by more than the infused volume. The colloid osmotic pressure remains elevated two to five days following HES infusion, corresponding to the plasma half-life of HES.

As would be predicted from its efficacy as a plasma volume expander, HES infusion has good hemodynamic effect. In comparative studies of fluid therapy patients, infusing 6% HES solutions has increased central venous pressure, pulmonary capillary wedge pressure, cardiac output and ventricular stroke work, with efficacy equivalent to that of 5% albumin infusion.[28,35,36] There have been no reported bleeding problems in these studies, even in perioperative patients. HES has also been successfully used as a priming solution for cardiopulmonary bypass. Although a comparative study showed that postbypass platelet counts were lower following HES compared with albumin prime, no difference occurred in chest tube drainage, blood use, hemoglobin or fibrinogen levels or coagulation times.[37]

In comparison with dextran, HES has similarities and differences. Both dextran and HES effectively raise colloid osmotic pressure and plasma volume, though the plasma volume increase may be greater and somewhat more sustained following infusion of higher molecular weight dextrans. Dextrans are more useful agents in decreasing blood viscosity and increasing microcirculatory blood flow, and thus have advantage as antithrombotic agents and as therapy for microcirculatory flow disturbances. HES, on the other hand, appears to be associated with fewer adverse effects, including a lower incidence of anaphylaxis, fewer bleeding problems and no adverse renal effects. Current 1985 costs to our hospital for 500 ml of 6% HES is about $40 compared with $27 for dextran 40 and $106 for 5% albumin.

Perfluorochemicals

Perfluorochemicals (PFCs) are 8 to 10 carbon fluorinated hydrocarbons. Oxygen is highly soluble in liquid PFC, and this inspired the concept that these substances might prove useful as "artificial blood."[38] However, PFCs are immiscible in aqueous solutions, including plasma. Thus, its potential use as a blood substitute has been delayed by the necessity of suspending PFC in an emulsion suitable for intravascular infusion.

In 1968, total exchange transfusions in animals were successfully done using such a PFC emulsion.[39] There were, however, significant problems with these early emulsions, including prolonged tissue retention times and pulmonary and hepatic toxicity.[40] During the 1970s, Japanese workers developed an improved emulsion, named "Fluosol-DA 20%" (Fluosol).[41] This emulsion is 20% PFC by weight and uses two PFC molecules, perfluorodecalin and perfluorotripropylamine. Poloxamer 188 (Pluronic F-68) and egg yolk phospholipid are emulsifying agents, and hydroxyethyl starch is added to increase oncotic pressure. Fluosol must be stored frozen and infused within 24 hours after thawing.

Perfluorochemical emulsions are eliminated unchanged through the airways. The particle size of the Fluosol-DA emulsion is quite small, with a mean diameter of 0.1 micron, which contributes to elimination through the alveolar membrane. (There are other advantages to this small emulsion particle size, as will be discussed.) There is also some uptake of PFC emulsions by the reticuloendothelial cells. The plasma half-life of Fluosol is about 17 hours after infusion of 20 ml per kg.[42,43]

Because oxygen is dissolved in PFC emulsions, not bound as it is to hemoglobin, the amount of oxygen transported depends on the partial pressure of oxygen in the arterial blood (Pa_{O_2}). Although PFCs have about 20 times the solubility for oxygen as plasma, significant volumes of oxygen are still only dissolved at high Pa_{O_2} values. Thus the clinical use of PFC emulsions requires good pulmonary function and high inspired oxygen concentrations. An advantage of this relatively low "affinity" of PFC for oxygen is that nearly all oxygen dissolved in PFC at arterial oxygen tensions will be released to peripheral tissues at tissue oxygen tensions.

Plasma volume expansion is an important aspect of why PFC emulsions improve oxygen transport. Beyond simple

preload increase, however, the PFC emulsions may improve peripheral blood flow by improved microcirculatory flow. The small PFC emulsion particles (1/70th the size of erythrocytes) may flow through constricted areas of the microcirculation not accessible to erythrocytes. This may improve peripheral tissue oxygenation both by delivering oxygen dissolved in the PFC and by increasing plasma flow and delivery of that oxygen dissolved in plasma.

Fluosol was given to normal volunteers and tested in clinical trials in Japan in 1978.[44,45] It was first used in the United States in 1979, and limited clinical trials have since been undertaken, largely in anemic and bleeding patients who refused blood on religious grounds. There are limited published physiologic data on the efficacy of Fluosol infusion in terms of plasma expansion and oxygen transport. Mitsuno and coworkers reported that Fluosol infusion did result in significant plasma volume expansion.[46] Tremper and colleagues and Waxman and associates reported small series of anemic patients who had some improvement in oxygen delivery and oxygen consumption following Fluosol administration.[47,48]

A number of adverse effects have been possibly related to administering PFC emulsion. These include transient leukopenia, elevated liver function test values, increased pulmonary arterial pressures, transient hypotension and pulmonary failure.[48-50] It appears likely that an emulsifying agent in Fluosol, poloxamer 188, may be responsible for some of these adverse effects.[51]

The clinical usefulness of currently available PFC emulsions as a blood substitute has thus not been well established. A number of limitations of these solutions appear to be problems. First, the volumes of PFC emulsion that have been infused have been quite limited, and with these volumes only a relatively small amount of oxygen can be dissolved. (Even these small amounts might be important, however, in a critically anemic patient.) Second, the plasma half-life is relatively short. Third, in order for Fluosol to dissolve significant volumes of oxygen, very high Pao_2 tensions must be achieved and, therefore, adequate pulmonary function and high inspired oxygen concentrations are necessary. Finally, a number of possible adverse effects following Fluosol administration have been reported; the incidence and clinical significance of these require further investigation.

Further work on PFC emulsions is ongoing and improved emulsions have already been described.[52] It is possible that at least some of the current limitations may be overcome and that PFC emulsions may prove to be extremely useful blood substitutes.

Interestingly, other possible clinical uses for PFC emulsions may have equal or greater promise. These include its use in cases of ischemic heart disease, cerebrovascular disease, peripheral vascular disease, wound healing, microsurgery and cancer therapy.

Stroma-Free Hemoglobin

For almost 70 years now, experimental work has been ongoing in an attempt to develop hemoglobin solutions as oxygen-carrying blood substitutes.[53-58] Human hemoglobin solutions offer a number of theoretical advantages, including the potential to develop a stable, oxygen-binding, colloid volume expander with no antigenicity. The development of clinically usable solutions, however, has been slow. The initial problem with hemoglobin solutions was renal toxicity; this has now been shown to be primarily due to the erythrocytic stromal components of the early hemoglobin preparations, not the hemoglobin itself.[59,60] This has led to the development of stroma-free hemoglobin solutions, which are highly purified hemoglobin solutions, with erythrocytic membrane fragments removed.

Problems with preparing purified stroma-free hemoglobin solutions have been carefully studied.[61] Currently utilized solutions are generally made from the hemolysis of washed, outdated, banked, human packed erythrocytes. This hemolysate is then sequentially crystallized and washed until pure crystalline hemoglobin is produced.[62,63] This protein may be stored in dry form or it may be reconstituted into a solution. While these preparations are relatively stable, there is a gradual breakdown to methemoglobin when they are stored at room temperature; shelf-life is greatly prolonged if stroma-free hemoglobin is stored frozen.[64]

A major possible advantage of stroma-free hemoglobin over other plasma expanders is the ability of hemoglobin to bind oxygen. A major problem, however, exists with the usual stroma-free hemoglobin preparations, increased affinity for oxygen compared with that for erythrocytes.[65] The oxygen half-saturation pressure (P-50) of stroma-free hemoglobin solutions varies from 12 to 16 torr compared with a value of 26 to 27 torr for fresh blood. This increased oxygen affinity (left-shifted oxygen-dissociation curve) is due to the loss of tetrameric hemoglobin, the lack of 2,3-diphosphoglycerate (2,3-DPG) and a higher pH compared with the intracellular erythrocyte pH. The increased affinity for oxygen by stroma-free hemoglobin solutions could lead to inadequate release of oxygen to the tissues, even in the face of adequate circulating volumes of oxygen. While this problem, indeed, is confirmed experimentally, still, in experimental models of shock, stroma-free hemoglobin solutions improve tissue oxygenation when compared with non-oxygen-carrying resuscitation fluids.[55,66,67]

Another major problem with stroma-free hemoglobin solutions is their rapid clearance from the vascular space due to renal excretion and reticuloendothelial cell uptake.[59-70] In experimental studies, stroma-free hemoglobin solutions have a plasma half-life of two to four hours. The rapid loss of hemoglobin molecules creates a further problem, as the effect is that of an osmotic diuretic and can result in intravascular volume depletion. To counteract these effects, a number of hemoglobin complexes have been described that result in a larger species with longer intravascular half-life. A disadvantage of most of these techniques, however, is that they tend to further lower the P-50. Most recently a complex of hemoglobin with pyridoxal-5′-phosphate has been described that reportedly increases both plasma half-life and P-50.[71] Stroma-free hemoglobin has also been encapsulated in artificially produced liposomes, simulating the erythrocytic membrane and allowing the addition of 2,3-DPG.[72] These "artificial erythrocytes" reportedly have normal oxygen-hemoglobin dissociation properties.

Although hemoglobin solutions have been used clinically in various parts of the world, there has been no clinical work evaluating plasma volume expansion and oxygen transport using the most recently developed stroma-free hemoglobin

preparations. Clearly, these solutions offer great potential advantage over other plasma expanders and blood substitutes and continued experimental work and the initiation of clinical trials are of major clinical interest.

Specialty Conference

Neurobiologic and Psychobiologic Mechanisms in Gastric Function and Ulceration

Moderator
HERBERT WEINER, MD

Discussants
DONALD NOVIN, PhD; CARLOS V. GRIJALVA, PhD; YVETTE TACHÉ, PhD, *and* THOMAS GARRICK, MD

An edited summary of an Interdepartmental Conference arranged by the Department of Medicine of the UCLA School of Medicine, Los Angeles. The Director of Conferences is William M. Pardridge, MD, Associate Professor of Medicine.

The initiation and termination of feeding behavior are not fully understood. The stomach has been implicated as one source of signals regulating food intake. The sight and smell of food are potent stimuli to gastric acid secretion and contraction. The mouth, upper gastrointestinal tract and liver contain receptors regulating food intake; afferent information passes into the brain stem and into the brain areas. Lateral hypothalamic lesions abolish feeding, raise the body temperature and basal gastric acid secretion and produce gastric erosions. Vagotomy and administering propantheline bromide abolish the increased acid secretion after such lesions; they also alter the mucosal barrier permitting diffusion of protons into mucosal cells. Several of the neuropeptides via the central nervous system stimulate or inhibit gastric acid secretion through modulation of the autonomic nervous system. Most animal models of gastric erosions are associated with a reduced body temperature. Unknown is whether or not this association is the result of increased levels of thyrotropin-releasing hormone—a potent stimulus to gastric acid secretion and erosion formation when injected intracisternally.

(Weiner H, Novin D, Grijalva CV, et al: Neurobiologic and psychobiologic mechanisms in gastric function and ulceration—Interdepartmental Conference, University of California, Los Angeles [Specialty Conference]. West J Med 1985 Aug; 143:207-222)

The Experimental Production of Gastric Erosion and Its Relation to Human Ulcer Disease

HERBERT WEINER, MD:* Our understanding of the cause and pathogenesis of a disease has often been furthered by the development and use of animal models. However, the pathogenetic mechanisms, anatomic site and nature of the lesion, pathophysiology and course of the disease produced in animal models do not mimic peptic ulcer disease in humans.

With rare exceptions,[1,2] experimental erosions produced in animals are located in either the gastric rumen[3] or fundus[4] and not in the duodenum. Until recently, it was believed that social, behavioral and psychologic factors played a negligible role in human gastric ulcer disease; its pathogenesis was mainly associated with atrophy or a decline in mucosal resistance, or both. Emulsifying agents[5] or drugs, such as indomethacin and salicylates, which inhibit prostaglandin synthesis, are also associated with gastric ulcers in humans and with gastric erosions in animals.[6]

Gastric erosions have also been experimentally produced in animals by many drugs such as histamine and pentagastrin, which increase gastric acid secretion, by starvation,[7] ligating the pylorus and bleeding of the animals.[8,9] Many behavioral techniques produce gastric ulcers: aversive stimulation,[10] conditioning techniques and immobilizing by restraint,[11,12]

ABBREVIATIONS USED IN TEXT

CCK8 = cholecystokinin 8
CGRP = calcitonin gene-related peptide
CNS = central nervous system
CRF = corticotropin-releasing factor
ODT8-SS = des-$AA^{1,2,4,5,12,13}$ [D-Trp^{8}] somatostatin
TRH = thyrotropin-releasing hormone

with or without cooling the animal.[13] Feeding a rat only once a day enhances its motor activity and in four to five days leads to weight loss, hypothermia and gastric ulceration.[14]

The ultimate aim in such studies is to determine the brain mechanisms that mediate the effects of behavioral interventions and result in altering the physiology of the stomach in such a manner that ulcers ensue. Lesions of the hypothalamus, particularly of the ventrolateral nucleus,[15] and of the hippocampus[16] have been shown to predispose to formation of a gastric ulcer. In animals, the effects of hippocampal lesions can be modified by concurrent stimulation of the medial forebrain bundle.[17] But as Dr Grijalva's discussion shows (see page 212), lateral hypothalamic lesions may produce gastric erosions by mechanisms that differ from those set into motion by other techniques, such as stimulating basal acid secretion and raising the body temperature.

The role of a fall in ambient and core body temperature seems to be critical in the production of many other forms of experimental gastric erosions.[18] Cooling animals enhances restraint-induced gastric erosions. A fall in body temperature probably mediates the effects of premature separation, nutritional and sleep deprivation and enhanced motor activity—all known to produce gastric erosions.

Gastric acid secretion is inversely related to ambient temperature,[19] even though core body and stomach temperatures remain unchanged.[18] At low ambient temperature the acid secretory response to insulin[19] and the release of pepsin are augmented, whereas mucus production decreases.[20] Lowering the core body temperature augments the acid output to histamine administration.[21] Increasing the vagal efferent discharge also increases gastric contractions and compresses the mucosa.

Rats prematurely separated at 15 days from their mothers are at particular risk for restraint-induced gastric erosions.[12] During restraint they cannot maintain body temperature. When these rats are maintained at an ambient temperature of 10°C, their acid output is no greater than normally weaned rats.[18] Therefore, it is not likely that gastric erosions in a prematurely separated rat are the product merely of an enhanced acid output. Other factors may likely play a role: a diminished mucosal resistance, a disruption of the normal ontogeny of acetyl choline, histamine or gastrin receptors or longer lasting and more powerful contractions of the stomach wall. These data suggest that the pathogenetic mechanisms for gastric erosions in rats have not been elucidated and that no single mechanism, or invariant set of mechanisms, is responsible for all forms. In fact, pathogenetic heterogeneity may be the rule.

In humans, gastric ulceration may occur after blood loss (as in rats) and burns, during which the core body temperature also falls. Prostaglandin inhibitors are also associated with gastric ulcers. Recently, two sets of data suggest that gastric ulcer disease in humans is associated with antecedent life changes, albeit not with the degree as that of peptic duodenal ulcer disease. Peters and Richardson reported that the onset of gastric ulcer disease was associated with dramatic events in the lives of two patients.[22] During the height of their symptoms, both basal and maximal stimulated acid output increased; with resolution of their personal problems, acid output fell and the symptoms of the disease disappeared.

Gastric ulcer disease in humans may not be one but several diseases, each with a different pathogenesis, as is the case with peptic duodenal ulcer disease.[23] This conclusion is supported by data from studies of gastric erosions in animal models that may recently have acquired more relevance for gastric (but not duodenal) ulceration in humans.

The Nature and Integration of Signals Controlling Food Intake

DONALD NOVIN, PHD:* Body weight in mature organisms results from a balance of energy intake and output. When intake exceeds output, the excess is conserved as fat deposits in the body. When the opposite occurs and output exceeds intake, nutrient stores (primarily fat) supply the energy substrates not available from exogenous sources—that is, food.

Why is it that for most people the difference between input and output integrated over some reasonable period of time (days or weeks) is equal to zero? And, why is it not for a significant number of other persons? These are difficult questions to answer. Consequently, feeding-related disorders, such as obesity and anorexia nervosa, are difficult to treat.

Energy intake should influence body weight. Other things being equal, the more calories one consumes, the more one will weigh; this is not a linear function, as increased caloric intake substantially increases heat loss, the so-called thermic effect of food.[24] The relative lack of this thermic effect in an obese person may contribute to that condition[25]—a controversial hypothesis.

That body fatness (or some correlate thereof) modifies food intake[26] has been shown experimentally in animals where the first meal after weight loss induced by starvation is larger than any previous spontaneous meal. Conversely, when animals have been fattened in various ways, spontaneous meals are considerably decreased in size.[27] Something about a change in weight (body fatness) alters the strength of signals for hunger and satiety. Because body weight or fatness, or both, fluctuate little with single meals, this variable operates on feeding through a biasing mechanism making other hunger and satiety signals more or less efficacious.

To understand feeding and weight disorders, we must know something of what these hunger and satiety cues might be (short-term control) and how long-term mechanisms (such as body fatness) affect them. Unfortunately, although progress has been made, we are far from a general theory of hunger and satiety.

Historical Perspective

There are three periods in the history of the science of feeding.

Gastric hypothesis. The first systematic theory of feeding was developed by Cannon[28] during the early 1900s and stated that feeding was stimulated by hunger pangs resulting from large stomach contractions and that satiety occurred as a func-

*Department of Psychology, UCLA.

tion of a quiescent stomach. It was supported by common sense and by some empirical evidence (Figure 1). Its decline as a leading theory occurred for various reasons. Stomach denervation and even gastrectomy, which had slight and transient effects on feeding, were some of the observations inconsistent with the theory.

Dual-center glucostatic hypothesis. Manipulation of the alimentary canal and its innervation yielded slight and transient effects, whereas stereotaxic surgery yielded great and seemingly permanent effects on feeding. This led to the second phase, beginning in the 1940s. Two areas of the hypothalamus were singled out on the basis of results of discrete lesion and electrical stimulation experiments made possible by the new technique; the lateral hypothalamic area became a center identified with hunger and the ventromedial nucleus of the hypothalamus with satiety. This concept, combined with the notion that the major signal was glucose use sensed by the ventromedial nucleus of the hypothalamus, became a powerful and stimulating theory of feeding (Figure 2).

The theory suffered because the notion of "centers" in the brain is misleading. Brain areas do not operate in isolation but as part of widely interconnected systems. It also became clear that there is considerable redundancy in the system. Thus, even after extensive hypothalamic destruction, feeding control is largely maintained.[29] No one organ or signal seems to be necessary for reasonable regulation to continue. For example, although regulation may occur in the absence of the stomach or its innervation, it is misleading to conclude that the stomach does not play an important role under normal circumstances. A simple dual-center system primarily responding to glucose metabolism did not fit enough of the experimental observations.

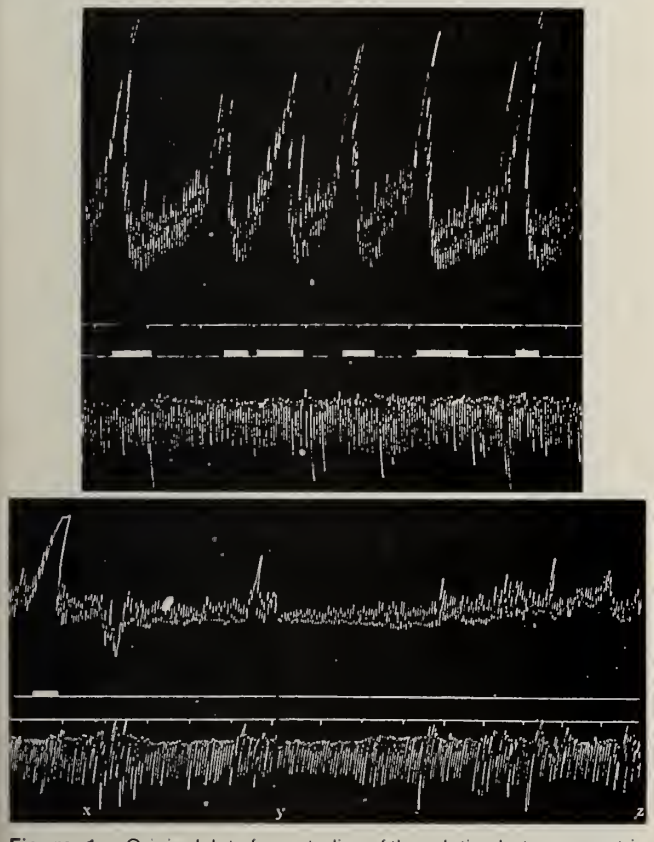

Figure 1.—Original data from studies of the relation between gastric activity and hunger sensations. The upper panel shows large stomach contractions (uppermost trace). Time signal is in 0.1 minutes (second trace). Key depressions indicate that subject felt hunger pangs (third trace) and respiration is shown (bottom trace). The lower panel is similar to the upper panel except there are few gastric contractions and few signals of the presence of hunger pangs (from Cannon[28]).

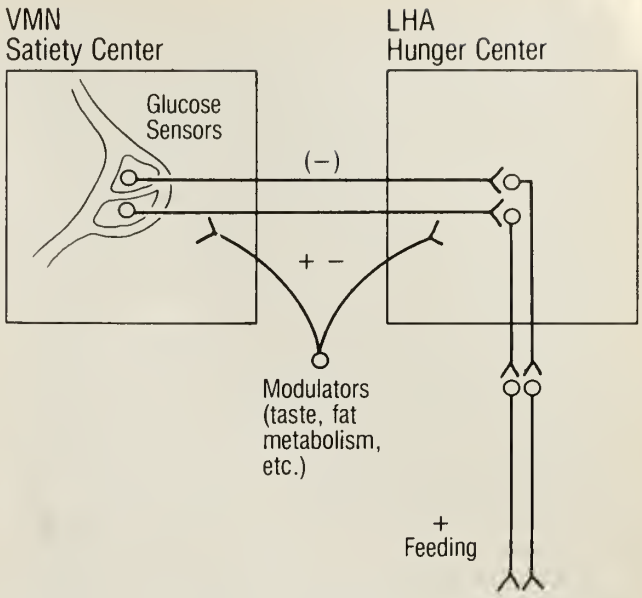

Figure 2.—A schematic of the glucostatic dual-center hypothesis. Ventromedial hypothalamic nuclei (VMN) satiety centers exert an inhibitory control over a lateral hypothalamic area (LHA) hunger center.

Peripheral and central loci for feeding control. The third phase in feeding research, begun in the 1960s, has been characterized by the attempt to find the organ, or area within or peripheral to the brain, that primarily controls feeding.

Oral factors play a major role in feeding. Although it was thought that they were dispensable, even that is not so clear.[30] Palatability cues exert great influence over energy intake. One can, for example, alter the level at which body weight is regulated by altering the palatability of the available food, an observation clearly shown in animals[31] and no doubt equally the case in humans.

Recently, Deutsch has resurrected the hypothesis that the stomach is a major source of signals controlling feeding.[32] He showed that food need only reach the stomach to provide potent quantitatively meaningful control over feeding. The implication for satiety is that food need not reach the gut nor even be absorbed (and reach other visceral organs or the brain) to provide adequate cues of satiety. Nevertheless, after gastrectomy, hunger as a sensation is retained and relatively normal body weight maintained.

The gut has also been implicated in feeding. One can introduce nutritive material via an intraduodenal cannula bypassing mouth and stomach and reduce subsequent intake. In some cases, this reduction may well be due to sickness or nausea, but in other situations it is likely that true satiety is induced. When hyperosmolar solutions such as 20% glucose are infused into the gut, sickness does ensue. On the other hand, isosmolar nutrient solutions such as 5% glucose will not cause malaise but will suppress food intake.[33] In addition, metabolic receptors have been found electrophysiologically in the gut.[34]

Russek proposed that the liver was the primary organ controlling food intake.[35] Again, it seems reasonable for the liver to be intimately involved in feeding control, particularly if one thinks of glucose metabolism as a primary concern of the feeding mechanism (the glucostatic hypothesis). The liver is the first line of defense of glucose homeostasis. It stores glucose when it is in excess (glycogenesis) and releases glucose molecules (glycogenolysis) or manufactures them (gluconeogenesis) when there is a need for glucose. The liver is also the first organ to sample much of the metabolite influx after absorption from the gut.

The hepatic theory of hunger and satiety has been controversial.[36] As in the gut, nutrient receptors are also present in the liver.[37] Interruption of pathways thought to innervate these receptors has been shown to alter feeding behavior.[38] Other investigators have found no effects of either putative complete liver denervation[39] or bypassing the liver after portacaval shunt.[40] Findings of experiments involving intravenous infusions of 2-deoxy-D-glucose, which blocks glucose uptake and use, have affirmed the liver's role in feeding. A shorter and more powerful hunger-inducing effect occurred when a hepatic-portal route was used compared with a systemic one.[41] Infusing nutrients such as glucose has yielded ambiguous results. At present, the role of the liver in controlling feeding remains moot.

Finally, the brain is also involved. The central nervous system (CNS) contains nutrient receptors, which are present in the hypothalamus and brain stem.[42] The existence of hypothalamic glucose-sensitive neurons strongly supports the dual-center glucostatic hypothesis. The behavioral evidence linking the hypothalamic glucoreceptors with feeding, however, is mixed. Infusing glucose or 2-deoxy-D-glucose by intracranial cannula into the hypothalamus has not delimited structures clearly involved in feeding. The results of gold thioglucose administration, a substance presumed to damage selectively ventromedial hypothalamic glucoreceptors causing hyperphagia and obesity, have also supported,[43] or been irrelevant to, the hypothesis of hypothalamic glucoreceptor control of feeding.[44]

In this third phase of theorizing about feeding controls, extensive and useful strides were made to reestablish the importance of events peripheral to the brain. The search for a sole or even primary locus of control has not been successful. At all levels from mouth to brain, important effects on feeding may be shown but none of the effects can be documented to be necessary or even primary.

Circulatory Agents

The discovery of the many gut, visceral and brain peptides and hormones has suggested the possibility that one or more of these could be hunger and satiety signals. At present two seem outstanding: cholecystokinin and glucagon; others are insulin,[45] bombesin[46] and endogenous opioids.[47]

Cholecystokinin is released from the gut in response to many components of a meal and in small quantities it reliably suppresses normal and sham feeding.[48] The interpretation of the results of feeding studies, however, is controversial. Does administering cholecystokinin suppress feeding through a satiety mechanism[48] or by producing nausea and malaise?[32] It would help to know what a physiologic dose of cholecystokinin is but reliable radioimmunoassay of cholecystokinin in blood is still not available.

Administering glucagon (another possible satiety agent) to animals fed spontaneously suppresses subsequent intake.[49] Glucagon is released in response to ingesting some components of food.[50] This result might be surprising because of its steady rise during starvation. However, Langhans and associates[51] have clearly shown a meal-induced rise and involvement of the hormone in satiety by showing that glycogenolysis occurred after a meal. They also found that administering glucagon antiserum reduced hepatic vein glucose concentration and increased meal size and duration in rats when compared with a control series of infused rats.[52]

We have shown that administering glucagon suppresses food intake when an animal is only minimally deprived[49]; it fails to do so if the animal is deprived of food for a longer time. This suggests that glucagon's suppressive effect depends on its action in causing hepatic glycogenolysis. Geary and colleagues have found other evidence to support this.[53] Finally, Martin and Novin showed that the glucagon-induced feeding depression depends on vagal innervation[49]; it disappears after subdiaphragmatic vagotomy.[54]

Although glucagon's action on feeding is not due to induced illness,[49] more sensitive tests are needed. Because the dosages used in the glucagon studies are high, the feeding effects may be pharmacologic rather than physiologic.

Neural Messages

Nutrient availability is certainly coded by chemoreceptors innervated by the autonomic nervous system. The first of these, taste, is also the best known. Norgren and Leonard[55] have uncovered the central neural pathways of the gustatory sense. But what of other chemoreceptors?

Because of the continuity of the alimentary canal, it is not surprising that there is electrophysiologic evidence for chemoreceptors in the gastrointestinal tract.[34] There is similar evidence from visceral nerve recordings for hepatic chemoreceptors, for mechanoreceptors and osmoreceptors in the gastrointestinal tract[56] and osmoreceptors in the liver.[57] Most of these findings are from recordings of vagal (parasympathetic) efferents,[56] but afferents also travel with the sympathetics.[34]

Results of studies in rats show that some visceral receptor inputs project to areas overlapping, and even converging, with the gustatory system (Figure 3).[37,55,58] The anterior pole of the nucleus tractus solitarius is the first relay nucleus of the gustatory system.[55] Visceral afferents project to a posterior region of the same nucleus some millimeters removed from the gustatory projections. Although these two systems do not converge directly at this level, Hermann and associates[58] have shown that both areas receive and give projections to the adjacent reticular formation. The next relay is at the pons in the parabrachial nucleus, the area Norgren and Leonard initially called the pontine taste area.[55] Hermann and co-workers[58] found that there are separate and convergent relays for gustatory and visceral inputs (Figure 3). In an earlier study, Hermann and Novin[59] showed that gustatory and visceral afferents converged in the parabrachial nucleus.

Grill and Norgren have shown that in rats this level of the neuraxis can subserve some surprisingly complex feeding behavior.[60] Normal rats characteristically accept palatable and reject unpalatable substances; these same responses are seen in decerebrate rats where everything above the pons is disconnected. Moreover, when satiated, decerebrate rats reject even previously palatable solutions, just as brain-intact rats do.

From the parabrachial nucleus both visceral and gustatory senses project to the ventrobasal complex of the thalamus, the analog of the classical sensory pathway. In addition, the parabrachial nucleus projects to hypothalamic and limbic system structures and directly to the cortex. Visceral afferents, particularly from an hepatic glucose-sensitive system, converge onto iontophoretically identified glucose-sensitive cells in the lateral hypothalamus.[61] Thus, at the hypothalamic level central and peripheral nutrient receptors interact.

Behavioral evidence shows that this level is required for even simple learning about taste-visceral connections. Thus, an intact animal will easily learn to reject even innately palatable tastes that are followed by an induced illness. A decerebrate rat does not learn this.[60] Ventrobasal complex lesions alone also prevent this type of learning. It seems, then, that behavior requiring "hard-wired" gustatory-visceral connections need only use brain-stem circuitry, whereas learned modifications of feeding behavior require higher levels of the nervous system. Whereas thalamic and hypothalamic mechanisms are all that are needed to subserve simple learning, long-term retention of learned feeding behavior may require the cortex (Philip S. Lasiter, PhD, Department of Psychology, UCLA, oral communication, March 1983).

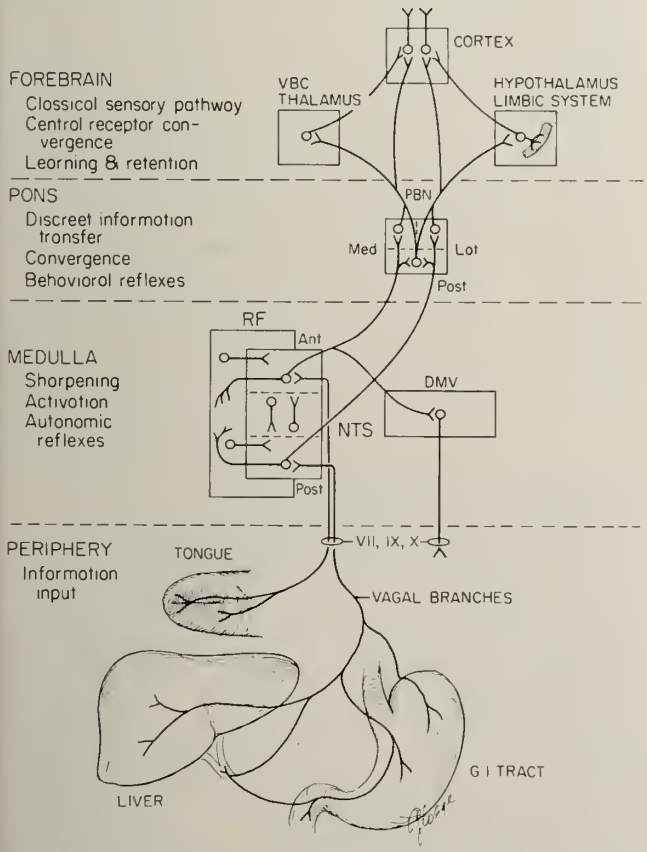

Figure 3.—A schematic of our current knowledge of the gustatory and visceral afferent pathways—the neural circuitry of feeding—in the brain. This suggests a hierarchy of processing, more complex information and behavior being subserved by higher levels of the neuraxis. (Adapted from Niijima,[37] Norgren and Leonard,[55] Hermann et al[58] and P. S. Lasiter, PhD, Department of Psychology, UCLA, and R. C. Rogers, PhD, Department of Physiology, Northwestern University Medical School, Evanston, Ill, oral communication, March 1983). DMV = dorsal motor nucleus of the vagus, G.I. = gastrointestinal, NTS = nucleus of the tractus solitarius, PBN = parabrachial nucleus, RF = reticular formation, VBC = ventrobasal complex

Much still needs to be learned about the neural substrates of feeding and their behavioral correlates. Nevertheless, several points are suggested by our current knowledge of these central pathways. At all levels of the CNS there is accurate information transfer and perhaps sharpening. At the same time, information may converge from different but equally relevant inputs as one ascends the nervous system. Simple autonomic and behavioral reflexes are organized at rather low levels of the CNS, some of which require integration of gustatory and visceral inputs. Learned behaviors and behavior involving complex integration need diencephalic structures. Long-term retention of learned feeding behaviors may require the highest levels of the nervous system, the cortex. Feeding may be controlled by various neural mechanisms of increasing flexibility and complexity. It would, therefore, be useless to seek *the* feeding or satiety center. Feeding seems to be the result of widely connected peripheral and central neural structures subserving different aspects of feeding behavior.

Integrated Systems Approach

There seems to be good evidence that the entire upper alimentary canal, the liver and the brain provide input important in feeding regulation. Equally compelling is the evidence that none are necessary components of that regulation, except insofar as they are necessary for life. These arguments are outlined above.

If this is so, it strongly suggests a redundant system of multiple inputs. More than that, it is useful to recognize that alimentation is a sequence in which each step in the process is involved in preparing the next stage to function more adequately. Thus, the cephalic phase of secretion causes gastrointestinal and pancreatic activity that greatly aids in the proper use of ingested metabolites. None of the organs of alimentation or metabolism operates in isolation. This interdependence may be why it is so often difficult to assess the role on feeding of an isolated organ. For example, it is difficult to show that hepatic glucose infusion alone suppresses subsequent intake. In contrast, when oral intake is combined with hepatic infusion, the contribution to the suppressive effect of each on carbohydrate intake is clear (D. Novin, PhD, unpublished data, May 1984).

Consideration of the information transfer and processing reinforces the notion that we have to broaden our perspective from thinking of specific signals, isolated organs or neural "centers." The evidence suggests that the brain integrates diverse feeding information in a hierarchical organization. Simple behaviors and autonomic reflexes of considerable importance use the lowest levels of the neuraxis based on the afferent inputs organized at that level. As the behavior gets more complex, increasingly complex afferent input and integration are probably required and involve higher and higher levels of the nervous system.

To understand the complexities of feeding, we need to study how the relevant signals (taste, visceral senses and so on) are processed by those organs involved in feeding. It is also vital to know how this information is projected to and integrated by the brain to produce the finely tuned behavior that it is for most organisms. For a clinician involved in treating feeding disorders, this approach is the one most likely to lead to an understanding of why this complex and elaborate system, viable for most, so often fails in humans and leads to pathologic states.

Experimental Gastric Ulceration After Lateral Hypothalamic Lesions

CARLOS V. GRIJALVA, PHD:* Although the cause of peptic ulcer is not well understood, it is thought that psychologic factors play a prominent role in the pathogenesis of some forms of the disease. Both clinical and experimental observations suggest that stress is a contributing factor[18]; a direct link between stress or other psychologic states and peptic ulcer disease remains to be elucidated, however.[62]

To identify the psychologic and behavioral components underlying peptic ulcer disease, some investigators have developed animal models that use various stress-provoking procedures. Although these approaches have been useful in showing an association between external or environmental factors and the presence of gastroduodenal abnormalities, the significance of this association remains equivocal because the underlying assumptions about what constitutes stress vary widely across experiments.

A different approach to studying the psychologic components to stress and peptic ulcer disease has been to examine the role of the nervous system. Although considerable advances have been made in establishing the relation between the central and autonomic nervous systems and gastrointestinal functions, our knowledge of the relative importance of specific brain regions and neural pathways remains fragmentary. Several cortical and subcortical structures have been implicated in the mediation of gastrointestinal functions, but most investigations have concentrated on the hypothalamus and its associated pathways.[15,63] This is not surprising given the close anatomic and functional relation between the hypothalamus and autonomic-endocrine systems.[64] One area of the brain that seems to be intimately involved in ingestive and digestive functions is the lateral hypothalamus.

Lateral Hypothalamus and Ingestion

The lateral hypothalamus has long been thought of as the feeding center because electrical or chemical stimulation of the lateral hypothalamus could induce eating in satiated animals and because damage to this area produced severe feeding and drinking deficits that seemed to be a function of the amount of lateral hypothalamic tissue destroyed.[65] It is now well established that although neurons within the lateral hypothalamic area may participate in ingestive behaviors, many of the acute and chronic dysfunctions in feeding and drinking after damage to the lateral hypothalamus are due to disruption of fibers of passage coursing through the area.[66] Furthermore, many of the effects that such lesions have on ingestive behaviors are closely related to alterations in general metabolism, energy homeostasis and autonomic functions.[67]

Lateral Hypothalamic Involvement in Gastric Acid and Gastrin Secretion

The results of several studies indicate that the lateral hypothalamus is involved in gastric acid secretion. In 1966 Misher and Brooks reported that electrical stimulation of the lateral hypothalamus in rats increased gastric secretion and acidity, which could be abolished by bilateral vagotomy.[68] Osumi and colleagues replicated this initial finding and further showed that electrical stimulation of the lateral hypothalamus also increased gastric mucosal blood flow.[69] Electrical stimulation of the lateral hypothalamus in cats also has increased gastric acid secretion, but these effects seem equivocal.[70]

Several studies provided additional support for lateral hypothalamic mediation of gastric acid release. For example, Colin-Jones and Himsworth showed that gastric acid secretion in rats was increased after administering 2-deoxy-D-glucose to the lateral hypothalamus.[71] This increase was prevented by raising the blood glucose concentration and by vagotomy. In addition, increases in gastric acid secretion induced by insulin or 3-0-methyl-glucose could be blocked by anesthetization of the lateral hypothalamic area with phenol or lidocaine.

Davis and associates found that lesions of the lateral anterior hypothalamus in dogs produced a significant increase in basal gastric acid secretion and these lesions blocked the gastric hypersecretory response to insulin.[72] Lesions placed just medial (paraventricular region) to the lateral anterior hypothalamus did not affect gastric secretion. In cats, lesions of the lateral hypothalamus and medial forebrain bundle have attenuated or abolished the increases in gastric acid secretion induced by insulin hypoglycemia or cytoglucopenia caused by systemically administered 2-deoxy-D-glucose.[73] Lesions placed immediately rostral, medial or dorsal to the lateral hypothalamus do not seem to alter the effect of 2-deoxy-D-glucose on gastric secretion. Michael Ruppel, MA, and Ernest Lindholm, PhD, Arizona State University, found that the initial periods of aphagia or hypophagia in rats resulting from lateral hypothalamic lesions were associated with increases in the volume of gastric secretion (unpublished data, December 1976). We have recently shown that the gastric secretory volume and acidity are significantly increased within two hours after lateral hypothalamic lesions.[74] On the other hand, Opsahl and Powley suggest that the long-term effect of lateral hypothalamic damage in rats is to reduce basal levels of gastric acid secretion.[75] These findings indicate that the immediate effects of lateral hypothalamic lesions may be related to an abrupt increase in neural activity of cells affected by the irritative property of electrolytic lesions and, thus, may mimic the effects of electrical stimulation.

Apart from electrical stimulation or lesions studies, there is evidence suggesting that the lateral hypothalamic area may be a site of action for certain neuropeptides that are implicated in the regulation of gastric secretion. Tepperman and Evered showed that microinjections of pentagastrin or natural gastrin into the lateral hypothalamus of conscious rats significantly increased gastric acid secretion, which could be blocked by atropine and by vagotomy.[76] Furthermore, similar doses injected intravenously or into other forebrain structures did not affect gastric secretion. Intrahypothalamic infusions of neurotensin, substance P and vasoactive intestinal polypeptide did not alter gastric secretion; infusions of bombesin into the lateral hypothalamus, however, decreased gastric acid output.

Both gastrin and bombesin may exert their effect by influencing neurons within the lateral hypothalamus; it is unlikely, however, that the lateral hypothalamus is the only site of action for these peptides. We have shown that intracisternal injection of bombesin, a tetradecapeptide originally isolated from the skin of frogs and found in mammalian gut and brain,

*Department of Psychology and the Center for Ulcer Research and Education, Veterans Administration (VA) Wadsworth Medical Center, UCLA.

attenuates the increase in gastric acid secretion induced by acute lateral hypothalamic lesions.[74] Intracisternal injections of bombesin, however, significantly increase circulating levels of gastrin,[77] and lateral hypothalamic lesions block this effect (Figure 4). Bilateral parasagittal knife cuts placed lateral to the lateral hypothalamus or coronal knife cuts placed posterior to the lateral hypothalamus also had similar effects on bombesin-induced hypergastrinemia.[78] These findings suggest that although the lateral hypothalamic area is not necessary for the expression of the inhibitory action of bombesin on gastric acid secretion, it seems to be directly involved in the effects that bombesin exerts on circulating levels of gastrin.

Lateral Hypothalamus and Gastric Mucosal Damage

In their initial studies on feeding behavior after lateral hypothalamic lesions, Teitelbaum and Epstein found on postmortem examination of rats who had died after a period of aphagia that some animals showed massive stomach ulceration and hemorrhage.[29] Although the gastric ulcers reported by them may have been related to the effects of starvation induced by lateral hypothalamic damage, in 1975 Lindholm and colleagues showed that bilateral lateral hypothalamic lesions (Figure 5) induced gastric mucosal damage within 24 hours postoperatively.[79] The severity increased during a four-day postoperative observation period, and this effect could not be accounted for by food and water deprivation alone. Furthermore, similar-sized lesions of the overlying thalamus did not induce gastric ulcers.

In further studies in our laboratory, we examined the effects of preoperative weight reduction on the incidence of gastric mucosal damage induced by lateral hypothalamic lesions. In one study[80] the weights of rats were reduced slowly by restricting daily food intake for two weeks, or rapidly by fasting totally for six days. Both groups of rats were reduced to the same body weight before lateral hypothalamic lesions were made. Rats either maintained at a normal body weight or preoperatively rapidly starved to 80% of their normal body weight showed ulcers and erosions of the glandular portion of the stomach after lateral hypothalamic damage. Rats preoperatively dieted slowly to 80% of their normal weight showed virtually no gastric ulceration after the brain damage. In addition to gastric ulcers, rats with lateral hypothalamic lesions showed hypersalivation, abnormal lacrimation and hyperthermia. We found that preoperative weight reduction from 5% to 25% of normal weight produced by dieting regimens was enough to attenuate these disorders to varying degrees.[81] Lateral hypothalamic lesions are associated with initial increases in metabolic rate; restricted feeding schedules, which reduce body weight, may provide some protection by altering the metabolic rate.

In attempting to elucidate some of the possible mechanisms underlying gastric mucosal damage after lateral hypothalamic lesions in rats, we have shown that the incidence of gastric erosions can be reduced significantly by subdiaphrag-

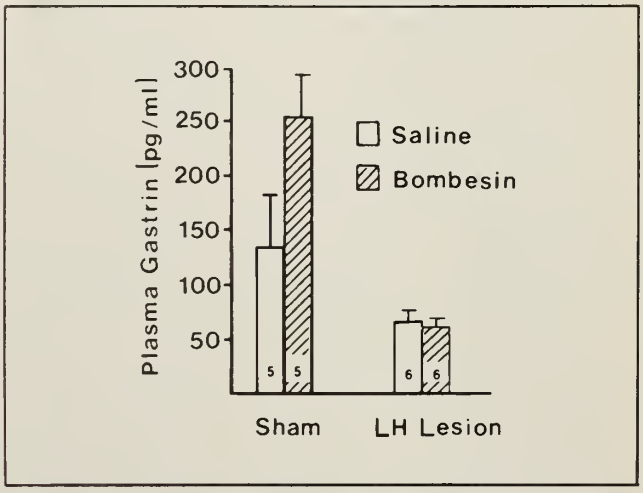

Figure 4.—The effect of intracisternal administration of bombesin (500 ng) alone or in combination with lateral hypothalamic (LH) lesions on blood gastrin in rats. Columns represent means and standard errors.

matic vagotomy or by administering propantheline bromide (anticholinergic), cimetidine (H_2-receptor antagonist)[82] or the antimuscarinic agent, pirenzepine,[83] all of which reduce gastric acid secretion. Only propantheline bromide also prevented the occurrence of hypersalivation and increases in lacrimation, indicating that a primary effect of lateral hypothalamic lesions is to produce an abrupt increase in parasympathetic activity. Tordoff and colleagues examined the effects of splanchnicectomy, celiac ganglionectomy, adrenal demedullation, adrenalectomy or chemical sympathectomy with guanethidine on gastric ulceration induced by a lateral hypothalamic lesion and found that none of these procedures significantly altered the severity of ulceration.[84]

Gastric acid is an essential factor in the production of peptic ulcer, but abnormally high levels of acid or pepsin are not always found. The extent to which the aggressive action of gastric acid and pepsin is pathologic partly depends on the defensive properties of the gastric mucosal barrier. The gastric mucosal barrier has been defined as the property of the gastric mucosa that impedes diffusion of acid from the lumen into the mucosa and impedes diffusion of sodium ions from the mucosal interstitial space into the lumen. We recently reported that significant changes in gastric mucosal barrier functions occurred within as little as three hours after lateral hypothalamic lesions.[82] These changes were indicated by a small but significant reduction in gastric transmucosal potential difference and a significant increase in hydrogen ion loss and sodium gain from the gastric contents. Furthermore, when sacrificed three hours postoperatively, only two of seven rats with lateral hypothalamic lesions showed gross gastric defects, whereas all seven rats showed similar alterations in barrier functions. Werther and Horowitz have reported similar changes in gastric mucosal barrier properties after restraint-stress in rats,[85] suggesting that both restraint-stress and certain forms of brain damage may produce gastric abnormalities by inducing similar pathophysiologic changes in the gut.

Gastric ulceration and gastritis have also been associated with the reflux of bile into the stomach that, in turn, seems to be related to the effects that bile salts have on the gastric mucosal barrier. Gastric mucosal damage in rats induced by lateral hypothalamic lesions can be blocked by bile duct ligation.[86] This finding suggests that the reflux of bile into the stomach in animals with lateral hypothalamic lesions may interact with a weakened gastric mucosal barrier to facilitate erosion and ulceration.

Studies are currently in progress to investigate some of the possible limbic system structures and neural pathways mediating the effects that lateral hypothalamic lesions have on the gastrointestinal tract. In a series of studies Henke has shown that the severity of gastric ulcers in rats can either be attenuated or facilitated by lesions in different structures with the limbic system.[87] One limbic system structure that has been implicated in emotionality and responsivity to stress is the amygdala. The severity of gastric ulceration in rats produced by physical restraint could be attenuated by prior lesions of the centromedial amygdala. Recent autoradiographic studies have shown ascending projections from the lateral hypothalamic area to the region of the central nucleus of the amygdala in rats.[88] This anatomic connection between the lateral hypothalamus and amygdala seems to be functionally related to gastric processes. We produced bilateral electrolytic lesions of the centromedial amygdala in 12 rats, while another group of 12 rats underwent a sham operation (C. Grijalva, PhD, and P. J. Geiselman, PhD, unpublished data, March 1980). Six to eight weeks later both groups were given bilateral lateral hypothalamic lesions, fasted for 24 hours postoperatively, sacrificed and their stomachs examined for abnormalities. Figure 6 shows an example of the combined lateral hypothalamus and amygdaloid lesions. Prior centromedial amygdaloid lesions (Figure 7) significantly attenuated the severity of gastric mucosal damage induced by lesions of the lateral hypothalamic area. We have recently found that centromedial amygdaloid lesions reduce gastric acid secretion,[89] and this may be a mechanism by which these brain lesions exert their protective effect on both stress-induced and hypothalamically induced gastric ulcers.

The lateral hypothalamic area in various species is inti-

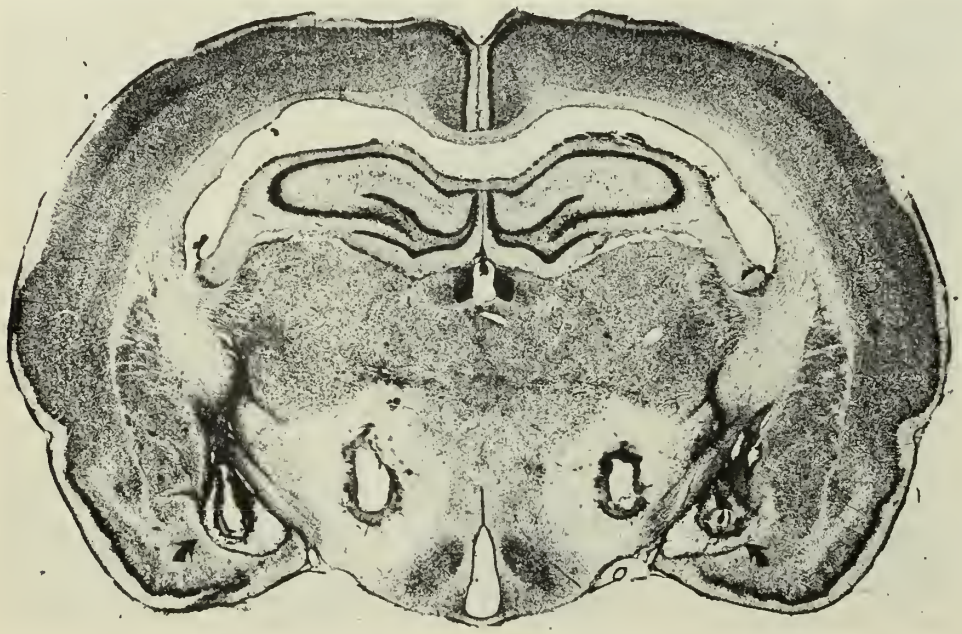

Figure 6.—Photomicrograph of a coronal section taken through the rostrocaudal midpoint of bilaterally placed centromedial amygdaloid lesions (indicated by arrows) and lateral hypothalamic lesions in the rat (thionin stain, original magnification × 6).

mately involved in regulating gastrointestinal function. Part of this involvement may be mediated by its connection with the autonomic nervous system and by its anatomic connections with limbic system structures implicated in emotional behaviors. The extent to which one can extrapolate findings in animal models to those in humans is presently unclear; however, studies such as the ones described may elucidate some of the underlying neural, peptidergic and behavioral processes involved in certain forms of peptic ulcer disease in humans.

Role of Brain Neuropeptides in the Regulation of Gastric Secretion

YVETTE TACHÉ, PHD:* During the past decades, literature reviewed by Grijalva and associates showed that electrical stimulations, or lesions of discrete brain area, elicited pronounced gastric morphologic and secretory changes. In these studies specific nervous structures and pathways influencing gastric function and the development of ulceration were identified. Little was known, however, about the biochemical signals acting on these brain sites that trigger gastric changes. Recently, the identification of neuropeptides in the brain and the gastrointestinal tract as a new class of intercellular messengers has given new impetus for understanding brain-gut interaction. We will focus on how neuropeptides influence gastric secretion (Table 1).

Neuropeptides That Stimulate Gastric Acid Secretion

Gastrin. The injection of pentagastrin (77 ng) into the lateral hypothalamus produced a transient increase of gastric acid output in rats with a gastric fistula. This response seemed to be specific for the lateral hypothalamus and was blocked by vagotomy or atropine, suggesting vagal-dependent neural pathways mediating gastrin's action.[76] However, gastrin (0.1 to 5 μg) or pentagastrin (0.2 μg) injected into the cerebrospinal fluid at the level of the cisterna magna or the lateral ventricle did not influence gastric secretion.[76,77,90]

The significance of gastrin acting centrally to stimulate gastric secretion has to be reconsidered because of the recent chemical identification of cholecystokinin 8 (CCK 8) in the brain. CCK 8 shares with gastrin complete homology of the C-terminal pentapeptide fragment and has accounted for the so-called gastrinlike immunoreactivity reported earlier in the brain.[91] Studies with the naturally occurring CCK 8 peptide, for which specific receptors have been found in the brain,[9] are needed to ascertain a possible central action of the cholecystokinin-gastrin family in controlling gastric secretion.

Somatostatin analogs. Intracisternal injection of some oligosomatostatin analogs, like des-AA^{1,2,4,5,12,13} [D-Trp^{8}] somatostatin (ODT8-SS), increased the volume and acid output of gastric secretion in rats. No effect was found after systemic administration of the peptide. The stimulatory action of intracerebrally injected ODT8-SS was dose-dependent (0.1 to 1 μg), reversible, long lasting, specific and abolished by vagotomy or systemic administration of atropine.[93] Because intracisternally injected somatostatin 14 or 28 did not influence gastric secretion, these results raise the question of whether the reduction in chain length of somatostatin enhanced the penetration of the oligosomatostatin analogs to their sites of action on somatostatin receptors in the brain or, alternatively, whether such effects are unique selective properties of the peptides acting on other receptors unrelated to somatostatin.

Thyrotropin-releasing hormone (TRH). The tripeptide TRH, given intracisternally or intracerebroventricularly, greatly increased gastric secretion in rats.[94] The stimulatory action is rapid at onset, dose dependent (0.1 to 3 μg), long acting, reversible and is found in conscious or urethane-anesthetized rats (Figure 8).[94] The most stable TRH analog, *p*-Glu-His-(3,3′dimethyl)-Pro-NH_2, RX 77368, mimicked the effects of TRH, but could elicit gastric secretion at a dose as low as 3 ng given intracisternally in urethane-anesthetized rats with a gastric fistula.[95] Although some CNS effects of TRH are exerted by its metabolites, the CNS action of the peptide on gastric secretion is mediated by TRH itself.[95] The neurohumoral pathways through which TRH stimulated gastric acid secretion are unrelated to its hypophyseotropic effects but appear to be vagal dependent and expressed through cholinergic mechanisms.[94,95] This is further supported by evidence that TRH injected intracisternally increased vagal efferent discharges recorded from platinum electrodes hooked to the truncal vagal nerve.

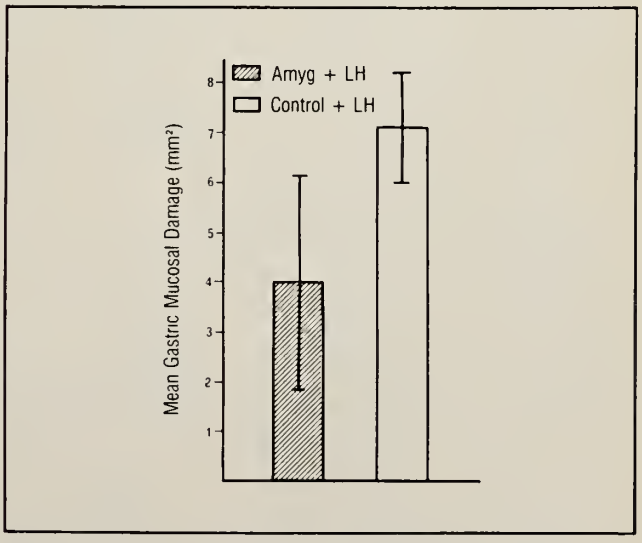

Figure 7.—This graph depicts the mean total area of glandular gastric mucosal damage in rats (N = 12 rats per group) sustaining either bilateral centromedial amygdaloid lesions (Amyg) and subsequent lateral hypothalamic (LH) lesions, or lateral hypothalamic lesions only. Both groups were examined for gastric abnormalities 24 hours after the lateral hypothalamic lesions.

High levels of TRH and its receptors have been characterized in the hypothalamus[96] and in the nucleus of the vagal complex,[97] providing a neuroanatomic substrate for confirming the role of brain TRH in modulating gastric function.

Neuropeptides That Inhibit Gastric Acid Secretion

Neurotensin. This tridecapeptide was isolated from the hypothalamus and like other neuropeptides, has a characteristic distribution with a highly individual neuronal circuitry in hypothalamic and extrahypothalamic structures. Autoradiographic localization of neurotensin-binding sites paralleled that of the regional distribution of the peptide.[98]

Neurotensin was the first peptide reported to decrease basal gastric acid secretion after intracerebroventricular administration (1 to 10 μg) in urethane-anesthetized rats with a gastric fistula. Neurotensin action was abolished by 6-hydroxy dopamine or reserpine pretreatment, suggesting that central catecholamines are mediating neurotensin's action on gastric secretion.[99] Japanese investigators found that neurotensin injected into the lateral hypothalamus (0.5 μg) transiently suppressed insulin-induced acid secretion.[100] Those findings have not been confirmed by American groups, however.[76,101] Whether neurotensin in the brain may play a role in the control of gastric acid secretion remains questionable.

Bombesin-like peptides. Bombesin is a tetradecapeptide originally isolated from the skin of the frog, *Bombina bombina.* Its mammalian counterpart has been chemically characterized from porcine gut and called gastrin-releasing peptide. This 27-residue peptide shares a C-terminal decapeptide homology with the C-terminal decapeptide fragment of bombesin, except for an interchange of Gln/His in position 7.[102] Bombesin-like peptides are widely distributed in mammalian brain and spinal cord.[103,104] The specific binding of bombesin to rat brain membrane and the regional distribution of bombesin receptors have been described.[105]

Bombesin or gastrin-releasing peptide injected intracisternally greatly reduced gastric secretory volume and titratable acidity in rats.[77] The inhibitory action of the peptides was long lasting, reversible, specific and dose-dependent in doses ranging from 0.01 to 1 μg in rats. Doses of bombesin as low as 10 ng decreased by 60% gastric acid output; higher doses (0.5 to 1 μg) raised gastric pH values above neutrality in pylorus-ligated rats. The biologic activity of gastrin-releasing peptide is contained in the C-terminal octapeptide fragment of the molecule.[77] Bombesin injected into cerebrospinal fluid suppressed acid secretion in various animal species: albino or hooded rats,[74] cats[106] and dogs[107] studied either in a conscious state or anesthetized with ether, methohexital sodium, urethane or chloralose. Figure 9 shows that bombesin or gastrin-releasing peptide blocked or decreased gastric acid output stimulated by different secretagogues such as 2-deoxy-D-glucose, insulin, histamine,[77] pentagastrin, TRH,[77] γ-aminobutyric acid agonist muscimol and baclofen, prostaglandin E_2, ODT8-SS or cysteamine and by various surgical manipulations, such as pyloric ligation, acute lesions of the lateral hypothalamus, lesions of the ventromedial hypothalamus, gastric sympathectomy or electrical vagal stimulation.

The pathways through which bombesin exerted its action are CNS mediated because the peptide inhibited acid secretion when injected into the cerebrospinal fluid at the level of either the lateral or the fourth ventricle or the cisterna magna,[77,106,107] but not when given intravenously.[77,106] In further studies done in rats to explore brain sites sensitive to bombesin, the peptide produced a pronounced rise in gastric pH values and a decrease in secretory volume when microinjected into the paraventricular nucleus; injections into other hypothalamic nuclei (lateral, ventromedial) or other forebrain structures, however, failed to alter gastric secretion.[108] Using centrally acting specific receptors or synthesis blockers of biogenic amines, we have not been able to prove that bombesin's influence involved an interaction with brain catecholamine, dopamine or serotonin neurotransmitters.[109] Bombesin action on gastric acid secretion seems unrelated to other effects of the peptide on pituitary and adrenal secretion.[109] Cross-circulation experiments showed that gastric response to intracisternal administration of bombesin is not mediated

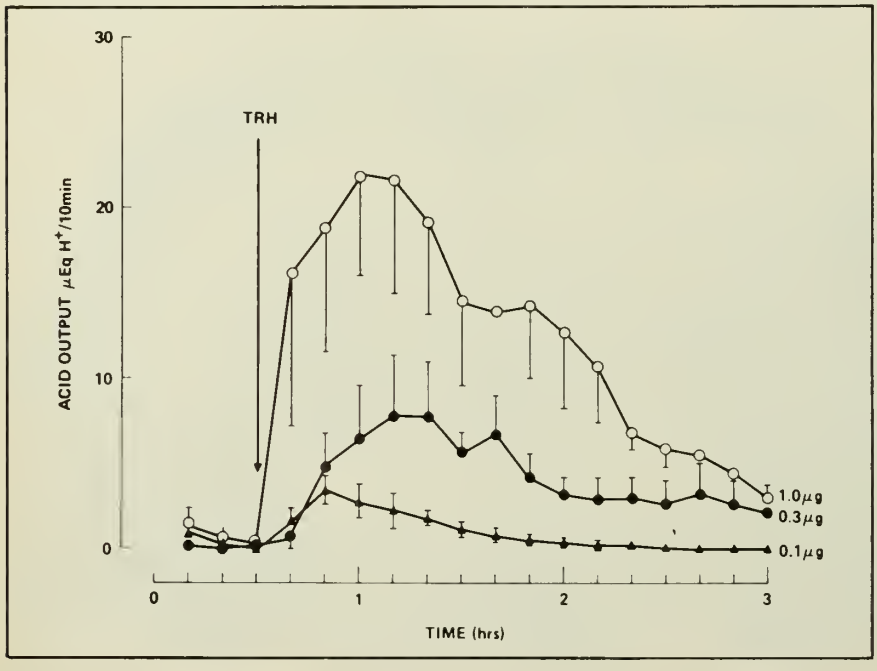

Figure 8.—Thyrotropin-releasing hormone (TRH), 0.1 to 1 μg injected intracisternally, stimulated gastric acid secretion in urethane-anesthetized rats with a gastric fistula. One hour after placement of a gastric fistula, the gastric lumen was flushed every 10 minutes with two 5-ml boluses of 0.15 mol per liter of sodium chloride and one 5-ml bolus of air. Acid output was determined by titration to pH 7.0 of the flushed perfusate. Each point represents the mean ± standard error of the mean of five to eight rats.

by humoral mechanisms. Bombesin effects were also independent of interaction with opiate receptors, prostaglandin generation and vagal activity. Pharmacologic and surgical approaches point to a mediation by the sympathetic nervous system because transection of the spinal cord up to the seventh cervical levels, or blockage of α_2- but not α- or β-adrenergic receptors, partly reversed the rise in gastric pH induced by intracisternal administration of bombesin.

Opioid peptides. The brain contains at least three anatomically separated neuronal networks of opioid peptides: an enkephalin, a β-endorphin and a dynorphin family.[110] Several distinct types of receptors (μ, γ, κ) for opiates have also recently been characterized in the brain.

The β-endorphin injected intracerebroventricularly or intracisternally inhibited gastric acid secretion in rats by decreasing gastric secretory volume and, to a lesser degree, titratable acidity under basal or TRH-stimulated conditions. The effect is dose dependent, in doses ranging from 0.8 to 25 μg, with 50% inhibition obtained with a 2.3 μg dose[111] and reversed by vagotomy.[112] The stable enkephalin analogs, D-Ala^2-Met-enkephalinamide (1 to 20 μg) or [D-Ala^2,Met-Phe^4,Met-(0)^{5}ol] enkephalin, FK33-824 (2 μg), injected intracerebroventricularly in rats suppressed gastric secretory volume and titratable acidity under a basal, TRH-, insulin- or muscimol-stimulated condition.[113] The tridecapeptide dynorphin (1 μg) has also produced similar inhibitory effects.[113]

Figure 9.—Bombesin (B) or gastrin-releasing peptide (GRP) (0.5 to 1 μg) injected intracisternally (IC) inhibited gastric acid secretion stimulated in rats by various chemical and surgical treatments. Secretagogues were given as indicated, simultaneously with bombesin or GRP, and then the pylorus was ligated. Two hours later, conscious rats, except pentagastrin-treated animals, were decapitated for collection of gastric secretion. Acid output was calculated by multiplying gastric secretory volume by the concentration of acid. Lateral hypothalamic (LH) lesions were done within two to four minutes before bombesin administration, ventromedial hypothalamic (VMH) lesions four days and gastric sympathectomy (Symp-X) five days before peptide injection. Pentagastrin was infused in urethane-anesthetized rats through the jugular vein (IV) and gastric secretion collected as described in the legend of Figure 8. Number of rats for each treatment regimen is shown at the bottom. Each column represents the mean ± standard error of the mean. IV = intravenously; PGE_2 = prostaglandin E_2; PO = orally (per os); SC = subcutaneously; SS analog (ODT8-SS) = des-AA^{1,2,4,5,12,13} [D-Trp^8]

The gastric response to intracerebral injection of all opioid peptides was reversed by naloxone pretreatment.

The brain or spinal sites, types of receptors and neurohumoral pathways involved in mediating the inhibitory effects of opiates remain unknown. The influence of selective blockade in the brain of various opioid receptors on basal and stimulated gastric secretion will clearly show the physiologic role of brain opioid peptides in regulating gastric function.

Corticotropin-releasing factor (CRF). CRF is a 41-amino acid peptide recently characterized from the hypothalamus. The peptide plays a physiologic role in the control of pituitary secretion of adrenocorticotropic hormone and β-endorphin.[114] Hypothalamic and extrahypothalamic distribution of CRF-like immunoreactive neurons has been extensively studied.

CRF injected into rat cisterna magna induced a dose-dependent inhibition of gastric acid secretion by reducing acid concentration and, to a lesser degree, secretory volume. Peptide action was dose dependent in a dose range of 1 to 10 μg, long acting and observed in conscious or urethane-anesthetized rats. CRF inhibited acid secretion stimulated by pentagastrin or intracisternal administration of TRH.[115] Microinjection of CRF (0.2 to 4 μg) in the ventromedial and paraventricular nucleus, and to a lesser extent the lateral hypothalamus, induced an elevation of gastric pH values and secretory volume and a decrease of gastric acid concentration and output in pylorus-ligated rats.[116] The sites sensitive to CRF seem to be those shown to have the highest content of CRF-like immunoreactivity outside the median eminence. The neurohumoral mechanisms through which intracisternally administered CRF inhibited acid secretion are unrelated to its pituitary effects but seem to be reversed by adrenalectomy, vagotomy or spinal cord transection at the fifth to the seventh cervical levels. The CRF action on gastric acid secretion is, therefore, probably mediated by modulation of the autonomic nervous system, involving a decrease in vagal tone and an increase in sympathetic outflow.[115] The inhibitory action of intravenously administered CRF is seen at higher doses and mediated by different mechanisms.[117]

The physiologic role of CRF has yet to be elucidated, but it seems to mimic the cardiovascular, endocrine and behavioral responses to stress and alters gastric secretion in a manner similar to that of various stressors.[114,115] Therefore, CRF may play a role in the gastric response to stress.

Calcitonin and calcitonin gene-related peptides. Recently Rosenfeld and co-workers[118] showed tissue-specific alternative RNA processing pathways in the expression of the rat calcitonin gene, and predicted a 37-residue peptide called calcitonin gene-related peptide (CGRP). The results of immunohistochemical studies and peptide isolation and characterization have supported the prediction that CGRP is present in the central nervous system.

Calcitonin. The calcitonin injected intracerebroventricularly suppressed both gastric secretory volume and titratable acidity in rats. The effect is dose dependent (41 to 416 ng), long lasting and CNS mediated because parenteral doses 1,000 times higher are required to obtain an inhibitory effect. Calcitonin given intracerebroventricularly suppressed acid secretion stimulated by TRH, muscimol or insulin.[119]

That immunoreactive calcitonin messenger RNA and calcitonin are not detected in rat brain or pituitary[118] casts doubt on a possible CNS action of endogenous calcitonin. However, high-affinity binding sites for calcitonin have been localized in various brain areas by autoradiography.[120] More information on the endogenous ligand for calcitonin receptors in the brain is needed to clarify the significance of these observations.

Calcitonin gene-related peptide. The peptide injected intracisternally in urethane-anesthetized rats inhibited acid secretion stimulated by pentagastrin or histamine in doses ranging from 50 to 500 ng. In conscious pylorus-ligated rats, CGRP given intracisternally (1 to 10 μg) or into the lateral hypothalamus (4 μg) suppressed gastric acidity and secretory volume. Peptide action is reversed by vagotomy but not by adrenalectomy or chemical sympathectomy elicited with guanethidine.[121]

Neuropeptides That Influence Pepsin, Mucus or Gastrin Secretion

Neuropeptides that act within the brain to influence acid secretion seem also able to modify other secretory functions of the stomach (mucus, pepsin, bicarbonate and gastrin).

Bombesin given intracisternally increased the amount of mucus coating the gastric wall through CNS-mediated and adrenal-dependent mechanisms.[109] Indirect evidence indicates also that the peptide enhanced bicarbonate secretion. The release of gastrin associated with intracisternal administration of bombesin in rats depends on the integrity of the lateral hypothalamus and the sympathetic nervous system.[78] Intracisternal administration of TRH increased pepsin secretion whereas bombesin decreased it.[95]

Conclusions

Several of the neuropeptides uniquely stimulate or inhibit gastric secretion (Table 1). Methods used for studying interactions between brain and gastric functions have been based exclusively on electrical stimulation or lesions of various brain structures. Such an approach has generated conflicting data, without determining whether the variations were due to differences in species, stimulation variables, lesion size or a combination of these.[15] Neuropeptides appear as new standard probes and provide alternative chemical approaches to study brain-gut relations. Through their use, new insight has already been achieved on brain structures such as the paraventricular nucleus, so far neglected and shown to be sensitive to bombesin, CRF and CGRP-induced inhibition of gastric acid secretion. Neuropeptides seem useful tools not only to map brain structures but also to dissect the neurohumoral mechanisms involved in the central control of gastric secretion. Moreover, the high potency of these peptides to affect gastric secretion and their presence and that of their receptors in brain structures involved in regulating gastric secretion provide a neuroanatomic substrate for the concept that the described biologic actions of some of these peptides may have a physiologic relevance in health and disease.

Role of Gastric Motility in Experimentally Induced Gastric Ulceration

THOMAS GARRICK, MD:* Experimental investigations of gastric erosions have generally focused on the balance between aggressive and defensive processes in the stomach. The aggressive factors are acid and pepsin secretion, physical abra-

*Department of Psychiatry and Biobehavioral Sciences, UCLA School of Medicine.

sion of the mucosa by food and the effects of ulcerogenic agents such as ethanol, taurocholate and nonsteroidal anti-inflammatory agents. The protective factors include mucus secretion, blood flow, regeneration and restitution of gastric cells, bicarbonate secretion and the prostaglandins. Although various animal models of gastric erosions have been developed to study pathophysiologic processes in a controlled setting and in intact animals, relatively little has been done to evaluate the role of gastric contractions in producing gastric erosions. This may be due to the technical difficulty of monitoring gastric motility at the time of lesion formation.

One of the most frequently used experimental models of gastric erosion was first described by Selye[122] in 1936, who found that prolonged restraint of food-deprived rats resulted in the production of gastric erosions. Since that time many variations of this procedure have been studied to investigate, in a controlled setting, the various factors promoting and preventing such lesions; subjecting a fasted rat to restraint in a cold environment has been a reliable method for inducing them.[123] The lesions produced are hemorrhagic, occur only in the glandular portion of the stomach and do not generally penetrate into the muscularis mucosa. Many investigators have examined the effects of these procedures on acid output and other physiologic processes. The literature is sharply divided on the association of cold-restraint lesion formation and acid hypersecretion.[18,124,125] Acid hypersecretion has been thought by some investigators to be pathogenetic in lesion formation in this model system[125]; others have documented no effect or even suppression of acid secretion.[124] Lesions continue to form, albeit to a lesser degree, when gastric acid is neutralized during cold restraint.[126] The local application of acid solutions alone does not result in the formation of lesions.[127] However, experimental procedures that usually prevent cold-restraint lesion formation, such as vagotomy and administering anticholinergic agents (atropine), also drastically change gastric motility.

Altered gastric motility has more and more been implicated in lesion formation in experimentally induced gastric erosions. The evidence for this is, to a large degree, indirect. Infusing papaverine hydrochloride (an antispasmodic agent) suppresses lesion formation without suppressing acid secretion. Mucosal erosions have been reported after experimentally inducing gastric spasm by vagal or direct electrical stimulation[128]; these experiments, however, were done without monitoring acid secretion.

The most common methods of measuring gastric motility are indirect. Luminal pressure can be monitored using catheters passed into the stomach. Alternatively, electrical correlates of motility can be acquired using electrodes that have a suction cup on the tip to grasp the mucosa. In animals, gastric motility is typically monitored using a balloon surgically introduced into the stomach immediately before experimentation. The balloon is inflated and connected to a pressure-monitoring apparatus. Using such techniques, consistent increases in the amplitude and frequency of gastric contractions have been found in animals undergoing cold restraint. Vagotomy, administering anticholinergic agents such as atropine and inhibition of smooth muscle contraction by papaverine HCl reduce gastric hypermotility and lesion formation. One of the difficulties in analyzing these results is that the techniques of monitoring motility are insensitive, prone to serious artifacts and do not accurately monitor the actual motility of subsections of the stomach. More important, these techniques do not permit observation of normal processes such as feeding that also stimulate gastric contractions and acid secretion but do not lead to lesions in the stomach.

To correct these errors, gastric motility was monitored directly using surgically implanted strain-gauge transducers developed by Paul Bass, PhD, of the University of Wisconsin. These transducers are implanted in animals long term to avoid the artifacts of a recent operation and anesthesia; they do not seem to interfere with the normal functioning of the stomach and rats need not be restrained during monitoring.[129] These transducers have been used to compare the motility patterns found during unrestrained feeding with those occurring during cold restraint and lesion formation in the same rat. The contractile activity found in rats fasted for 24 hours is characterized by low-amplitude contractions occurring at a frequency of three to four per minute, occasionally interrupted by brief bursts of high-amplitude contractions. The onset of feeding is associated with unmistakable increases in the amplitude of gastric contractions. These contractions occur with a rhythmic frequency of four to five contractions per minute (Figure 10). During the several hours after feeding, the occurrence of high-amplitude contractions progressively decreases; the basic contractile frequency remains about the same. High-amplitude contractions in a normothermic animal last about ten seconds in both fasted and fed states.

When animals are again fasted, restrained by wrapping them in wire mesh and immersed to the xyphoid process of the sternum in water maintained at 20°C for three hours, gastric erosions uniformly develop. During this period, they become hypothermic and gastric hypercontractility occurs. Specific patterns of gastric motility distinguish cold-restraint-induced hypercontractility from food-induced hypercontractility. The amplitude of the contractions is usually the same during both states, but the frequency of the patterns is distinctly different. Whereas the frequency of contractions during most phases of the feeding cycle is three to five contractions per minute, during prolonged cold restraint it consistently drops below

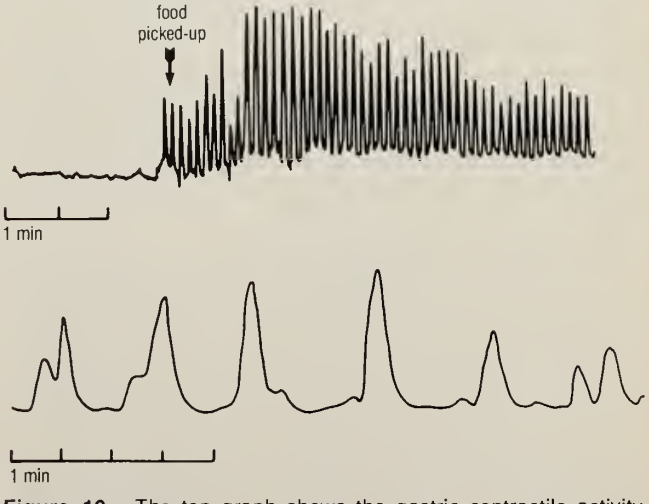

Figure 10.—The top graph shows the gastric contractile activity when a rat that has fasted for 24 hours starts to eat. The bottom reading shows gastric contractile activity when a 24-hour fasted rat is subjected to 3 hours of cold restraint at 20°C.

two contractions per minute. As the frequency of contractions drops, the average duration of high-amplitude contractions increases 200% to 400%, many contractions lasting 30 to 60 seconds (Figure 10).

Animals subjected to the same type of cold restraint were also prepared with gastric cannulas to monitor their acid secretory response. Uniformly, there was a gradual decrease in gastric acid secretion during the two hours of baseline and three hours of experimental conditions in control and experimental animals. The final acid secretory levels are significantly greater than zero and significantly less than baseline levels. Therefore, in this model, these procedures do not produce acid hypersecretion during lesion formation. However, the acid present may, as suggested by others,[127] still play a role in producing lesions. A pathophysiologic role for acid is evidenced by the definite decrease in lesion formation in animals treated with high-dose cimetidine or antacid solutions during cold restraint.[130]

The mechanism by which the described alteration in gastric motility results in mucosal lesions is not fully understood. Most of the evidence suggests that such contractions might result in a temporary restriction of blood flow to the mucosa, producing anoxic damage. The reduction of blood flow may be purely mechanical—tightly contracted muscularis constricts the small blood vessels traversing it. The restriction of blood flow might also involve vascular contraction or the shunting of blood away from the mucosa, thereby accentuating anoxic damage.[130,131] Postmortem examination of cold-stressed rats shows contracted stomachs with a blanched mucosa surrounding the erosions.[131] Such blanching is also seen during the formation of gastric erosions after vagal or local electrical stimulation.[128] Experimentally induced hemorrhage also results in mucosal lesions that closely resemble lesions after cold restraint. Cold-restraint lesions occurred only in the fundus of the stomach despite the fact that specific alterations in gastric contractility were also found in the antrum. This discrepancy may be accounted for on the basis of differences in blood flow: the antrum in both basal and stimulated conditions has a greater blood flow than does the corpus of the stomach.[132] Thus, fundic lesions may be more likely after such procedures than antral lesions.

In our experimental model, restraining animals in cold water produces gastric lesions without hypersecretion of acid. This procedure stimulates the onset of gastric contractions, the strength of which is comparable to those stimulated by food. However, the unusually prolonged duration of these contractions results in the stomach undergoing extended periods of contraction, which may play a role in the pathogenesis of mucosal erosions.

Medical Practice Question

EDITOR'S NOTE: *From time to time medical practice questions from organizations with a legitimate interest in the information are referred to the Scientific Board by the Quality Care Review Commission of the California Medical Association. The opinions offered are based on training, experience and literature reviewed by specialists. These opinions are, however, informational only and should not be interpreted as directives, instructions or policy statements.*

Radial Keratotomy

QUESTION:

Is radial keratotomy considered acceptable medical treatment for correction of myopia?

OPINION:

Although results from a carefully controlled, multicenter study indicate that radial keratotomy is a relatively safe and effective procedure for the correction of myopia in the short term, it is the opinion of the Scientific Advisory Panel on Ophthalmology that it should still be considered investigational. Results from the first year of the planned five year study, called the Prospective Evaluation of Radial Keratotomy (PERK), were made public in the fall of 1984.

It appears that radial keratotomy does have value for selected patients in reducing both myopia and dependence on the use of spectacles or contact lenses to correct that condition. However, the techniques of the procedure and its appropriate indications and contraindications are still evolving. Further, the procedure lacks an adequate level of predictability and, although small, there is some risk of permanent damage to the eye. Long-term results are unknown. The risks and complications should be detailed for all patients undergoing the procedure, particularly those whose motivation is purely cosmetic.

Until its long-term safety and effectiveness have been determined, therefore, this advisory panel feels that radial keratotomy should remain under investigation and should be done only with the approval and control of an institutional review committee.

Medical Staff Conference

Evaluating and Treating Intractable Cough

These discussions are selected from the weekly staff conferences in the Department of Medicine, University of California, San Francisco. Taken from transcriptions, they are prepared by Drs Homer A. Boushey, Associate Professor of Medicine, and David G. Warnock, Associate Professor of Medicine, under the direction of Dr Lloyd H. Smith, Jr, Professor of Medicine and formerly Chair of the Department of Medicine. Requests for reprints should be sent to the Department of Medicine, University of California, San Francisco, School of Medicine, San Francisco, CA 94143.

DR SMITH:* *The topic will be "Evaluating and Treating Intractable Cough," a rather intriguing title, and Dr Michael Stulbarg will give this presentation. Dr Stulbarg is Adjunct Associate Professor of Medicine and Chief of the Chest Clinic here.*

DR STULBARG:† Thank you, Dr Smith, ladies and gentlemen. Many patients seek medical care for the complaint of cough. In 1979 about 13 million people saw their physicians for evaluation of cough and, in fact, cough was the second most common reason given for seeing a physician. Most of these coughs are self-limited, but in a few persons the coughs are persistent, worrisome and sometimes even disabling.

I would like to begin with the report of a case that we recently labored over for several months. I think this case emphasizes the complex and at times frustratingly prolonged evaluation necessary to achieve a specific diagnosis for a patient with intractable cough. I shall then turn to the physiology of cough, the complications of cough (because these are what often bring a patient to a physician's attention), the diagnostic approach to cough, including the long differential diagnosis, and finally to treatment.

Report of a Case

The patient, a 30-year-old housewife from Manteca (California), was referred because of chronic cough of three to four years' duration with worsening over the past year. The cough began insidiously during pregnancy and had persisted since that time. She noticed that it increased with exertion, but she could relate it to no other factors such as position, time of day or meals. She also complained of a chronic "tickle" in her throat possibly related to postnasal drip and of occasional ill-defined episodes of "choking" both day and night. She had been seen by several physicians who had given empiric trials of antibiotics and steroids with no benefit. Codeine gave considerable relief, preventing her posttussive emesis and reducing the disruption of her sleep.

Past history of pertinence included drainage of a right frontal sinusitis and nasal septoplasty. She said she had no allergies or occupational exposures. One sister had hay fever. Although review of systems elicited a variety of nonspecific complaints, the most intriguing symptom was that of occasional difficulty swallowing solids but not liquids.

On physical examination she was mildly obese and had an occasional dry cough. Vital signs were normal. There was no inflammation of either tympanic membrane and no hairs impinging upon them. There was no bogginess, erythema or polyps of the nose, and the oropharynx was without cobblestoning or visible mucus. The neck was free of masses and the trachea was freely mobile. Her lungs were clear to percussion and auscultation. On cardiac examination there were a palpable pulmonic component of the second heart sound and a grade 2/6 systolic ejection murmur.

Several studies had already been done, the results of which were unrevealing; these included a hemogram, chemistry panel, chest x-ray films, allergy skin testing, bronchoscopy, esophagoscopy and otolaryngologic consultation. Because her evaluation had been so detailed, I was concerned that she might have one of the uncommon causes of cough such as interstitial lung disease or, because of her cardiac findings, occult heart disease. Further workup included a new chest film, which was normal, pulmonary function studies, the results of which were normal except for high flow rates (a finding of questionable significance), and echocardiogram, which showed mitral valve prolapse with normal left ventricular function. A gallium lung scan, done in the search for occult interstitial lung disease, was minimally and probably insignificantly abnormal. To determine whether the patient might have airway hyperreactivity characteristic of asthma, a histamine challenge test was done and was within normal limits.

Because the results of these studies were unrevealing, she then underwent noninvasive exercise testing looking for clear-cut cardiac or pulmonary dysfunction. Oxygen uptake and minute ventilation were measured in response to incremental exercise. Results of the test showed greatly abnormal exercise tolerance for a 30-year-old woman, with abnormal ventilatory and cardiac responses. Repeat exercise testing with measurement of arterial blood gases and wasted ventilation was technically inadequate but did confirm the results of

*Lloyd H. Smith, Jr, MD, Professor and formerly Chair, Department of Medicine.

†Michael Stulbarg, MD, Adjunct Associate Professor of Medicine, and Chief of Chest Clinic.

(Stulbarg M: Evaluating and treating intractable cough—Medical Staff Conference, University of California, San Francisco. West J Med 1985 Aug; 143:223-228)

ABBREVIATIONS USED IN TEXT

CT = computed tomographic [scan]
FEV_1 = forced expiratory volume in one second

the prior study. Because of the unexplained abnormal findings on exercise testing, cardiologic consultation was sought and the clinical assessment showed no abnormalities. She then underwent cardiac catheterization. As the results were normal, I discharged her with the hope that she would feel reassured that we had done "everything." However, she called a few weeks later still distressed because of persistent coughing, especially at night. She was readmitted to hospital with the hope that the house staff would come up with something that I had missed. Her laboratory values and chest film were still normal. The house staff suggested the possibility of psychogenic cough. The psychiatrist who evaluated her felt that she was mildly depressed and that the cough could be due to a conversion reaction.

At this time the complaints of dysphagia and occasional substernal discomfort began to draw our attention. Because of these complaints, she was instructed to maintain the head of her bed at 30 degrees of elevation both day and night. This seemed to be associated with a decrease in her cough, suggesting the possibility of esophageal disease. A barium swallow study was therefore done and the findings suggested the presence of a mass impinging on the esophagus. However, a computed tomographic (CT) scan of the chest was normal. Because these studies did not exclude esophageal reflux or esophagitis, esophagoscopy was done. Results of the study showed that she did in fact have distal esophagitis and antritis. Treatment with antacids and cimetidine led to a pronounced improvement in her cough, but it was not until a few months later when metoclopramide hydrochloride was added to her regimen that her cough actually *disappeared.*

I apologize for presenting this case at such length, but I wanted to emphasize both the effort and the satisfaction of reaching a specific diagnosis.

Physiology of Cough

Cough may be a voluntary event or an unsuppressible reflex.[1-3] It may result from stimulation of irritant or rapidly adapting receptors by mucus or environmental irritants.[2] These receptors are present throughout the respiratory tract from the upper airway including the nose, sinuses, oropharynx and larynx to the lower airway including the trachea and the carinae, both the main carina and the more distal divisions or subcarinae.[1] Following stimulation of these receptors, there is a sudden inspiration, followed in turn by the compressive phase. This phase is marked by tightening of the chest and abdominal muscles against a closed glottis, with a rise in pleural pressure to between 100 and 300 mm of mercury.[4] At some point, not well defined, the glottis suddenly opens, allowing the rapid noisy exhalation we call a cough. Because of the high intrathoracic pressure that has developed, there is considerable narrowing of the proximal airways and very high linear velocities, resulting in more effective expulsion of mucus or foreign materials than is produced by simple exhalation. The dramatic decrease in the cross-sectional area of the trachea may result in linear velocities in excess of three quarters the speed of sound.[5]

Complications of Cough

It is often the complications of cough that bring a patient to medical attention. The devastating personal distress and social isolation sometimes produced by severe chronic cough are frequently unappreciated. Many patients restrict their social lives and refuse to go to restaurants, theaters or public gatherings because of the embarrassment they experience from their cough. Disruption of family life is a common complaint. The patient who first piqued my interest in chronic cough was a woman whom I was asked to see in the intensive care unit. She had nearly successfully killed herself on two separate occasions because of the impact of an unremitting cough on her marriage.

More common complications include sleep disruption; musculoskeletal, chest or abdominal wall pain; emesis, and syncope.[1,6-15] The mechanism of emesis is not clear, but it is thought to be related to irritation of the oropharynx. Syncope, a particularly dangerous complication of coughing, may be due either to the effect of increased pleural pressure transmitted directly to the cerebrospinal fluid or to the Valsalva-like effect of increased intrathoracic pressure on venous return and the resultant hypotension.[11-15] The mechanical stress of coughing may cause elevations of creatine phosphokinase levels[10] as well as result in fractures of ribs.[16] The cough-induced tearing of abdominal muscles may mimic a ruptured abdominal viscus, and on rare occasions patients have actually undergone an unnecessary operation.[6-9]

Less common complications of cough include pneumothorax, mediastinal emphysema, pneumoperitoneum[17] and headache.[18] Though poorly documented, other rare complications noted in the past have included fatigue, physical exhaustion, anorexia and rupture of subconjunctival nasal and anal veins.[19] In a recent report, bleeding from esophageal varices induced by coughing was documented.[20] Though rarely mentioned as a complication,[19] stress incontinence precipitated by coughing has been a not-uncommon reason for referral in our experience.

Diagnostic Approach

In approaching the differential diagnosis of cough, it may be helpful to consider the locations of cough receptors, because disease in any of these sites might elicit cough.[1] These receptors occur in the ears, the nose and sinuses, the oropharynx, particularly around the larynx, the trachea and the bifurcations of the large airways.[1,2] They do not occur in the periphery of the lung, perhaps explaining why some patients with extensive pneumonia have little or no cough until they begin producing enough mucus to stimulate the more proximal cough receptors. Receptors are also said to occur in the pericardium, the diaphragm and the stomach,[1] though these must be of much lesser importance as cough is not an important symptom of diseases in those organs.

The diseases that may affect these sites are many. In only two studies have the causes of cough been carefully examined (Table 1). One study, reported in 1981 by Irwin and coworkers, is a prospective study of 49 patients presenting to a chest clinic with unexplained cough in a one-year period.[21] All of these patients had been seen by at least one previous physician and had defied diagnosis for at least three weeks. They developed clinical criteria that included response to specific therapy for each of their diagnoses. The second

study, by Poe and colleagues, was a retrospective review of patients with prolonged coughing (at least two months).[22] Their study was based on a review of charts, and the criteria for diagnosis were not as clear as those in the first study.

Particularly impressive in both studies is the high frequency of asthma—38% overall (Table 1). This diagnosis required the finding of obstruction by spirometry or, if none was present, an abnormal response to bronchial challenge.[23] As abnormal bronchial reactivity alone is not sufficient for a diagnosis of clinical asthma, response to specific therapy was also required. Another large group, 21%, had postnasal drip, a somewhat controversial diagnosis.[24,25] Patients with this problem report the sensation of mucus "dripping" into the throat and the need for frequent clearing of the throat (as opposed to a deeper chest cough).[25] Alone, or combined with asthma, postnasal drip accounted for 35% of the cases of cough in the study by Irwin and associates. The nine patients given both diagnoses responded only partially to therapy for one, but completely to therapy for both diagnoses. In total, then, more than 50% of the patients presenting with intractable cough had either postnasal drip, asthma or both.

Another major category in the second study was postinfectious cough. Such patients were not included in the series by Irwin and co-workers, perhaps because most of them would not have been referred or would have been considered asthmatic. In fact, some did have positive response to methacholine stimulation, but we do not know if they responded to bronchodilator therapy. It has been shown that abnormal bronchial reactivity may commonly persist for as long as two months after a viral infection and then resolve without therapy.[26] Bronchitis occurred in 12% of the patients, almost always in smokers, and was usually associated with nonreversible airway obstruction. In all of the cases where information was available, cough was greatly improved or disappeared after cessation of smoking, as has been previously reported.[27]

Esophageal disease represented a small but important minority of cases. The case described would clearly have fallen into this group. This diagnosis required abnormal barium esophagograms, endoscopy showing esophagitis or abnormal results on pH monitoring of the distal esophagus. In the combined series only one patient had cough due to lymphangitic spread of cancer[21] and one patient was found to have an endobronchial adenocarcinoma.[22] Although cardiac disease was rarely the explanation for chronic cough, in one patient the results of a cardiac catheterization did show left ventricular failure.[21] Interstitial disease of the lung was the cause of cough in only one patient.[21] In the retrospective series they could not identify a specific diagnosis in 11 patients, of whom 7 were considered to be of psychogenic origin, though the criteria for this assignation were not described.[22]

TABLE 1.—*Causes of Persistent Cough*

Causes	Studies: Irwin et al, 1981[21] Patients	Studies: Poe et al, 1982[22] Patients	Total Patients	Total Percent*
Asthma	12	39	51	(32)
Postnasal drip	14	9	23	(15)
Asthma plus postnasal drip	9	..	9	(6)
Postinfectious	..	27	27	(17)
Bronchitis	6	13	19	(12)
Esophageal	5	4	9	(6)
Cancer	1	3	4	(3)
Cardiac	1	3	4	(3)
Interstitial disease	1	..	1	(1)
Psychogenic	..	7	7	(4)
Undetermined	..	4	4	(3)
Total	49	109	158	

*Percentage does not equal 100 due to rounding of numbers.

This list is by no means complete, but it does reflect the most commonly reported causes of cough. Presumably any disease of the lungs or airways may on occasion present with cough. Other unusual causes have been reported. Removing residual sutures from a prior resectional operation resolved cough in one group of five patients.[28] Stimulation of the tympanic membrane by hairs in the auditory canal has caused recurrent severe coughing paroxysms that resolve within several days of removing the hair.[29] Cases of radiologically occult bronchiectasis[30] or an endobronchial nematode[31] may present with chronic cough. Inhaling toxic substances may seem an obvious cause of cough,[32] but patients often deny their regular use of tobacco or marijuana. We have seen several patients whose coughs were due to causes not clearly described previously. Several patients have had cough associated with unexplained dryness of their oropharyngeal mucous membranes. Finally, we have seen one patient with a postoperative neuroma of the glossopharyngeal nerve resulting in a disabling cough elicited by any superficial stimulation of the neuroma, such as touch or inhaling cold air.

Medical History

Though many of these diagnoses seem straightforward, it is evident that patients with intractable cough would not have been referred to a specialty clinic for evaluation if that were so. Irwin and colleagues found that a specific diagnosis could be made by an appropriate history alone 80% of the time.[21] Several historical points are worth emphasizing.

Identifying precipitating causes or time of onset of cough may be particularly helpful. For example, patients with esophageal problems, heart failure or asthma are more likely to cough at night. Patients with bronchitis or postnasal drip may complain of cough and sputum production early in the mornings. A relationship to meals may suggest esophageal disease. Cough related to interstitial lung disease or asthma often increases with deep breathing or exertion. Identifying exposures to allergens or irritants both at home and at work may relate to cough. A prior history of infections may be important. Viral infections may cause persistent cough for as long as a couple of months following the episode.[26] Patients with severe chest infections as children may be more prone to pulmonary disease in adulthood. Bronchiectasis may be clinically silent (dry) for many years and then become symptomatic in adult life following a respiratory tract infection.

Some medications may cause cough. β-Blockers given orally for cardiovascular disease or topically for glaucoma may precipitate asthma. A variety of drugs including chemotherapeutic agents and nitrofurantoin may cause interstitial lung disease. Awareness of a prior response to empiric treatment may be very helpful. Such treatment may have been appropriate, but physicians are reluctant to continue treatment with either steroids or antibiotics without a specific diagnosis.

On review of systems, one should pay particular attention to the much-neglected nose and sinuses. Postnasal drip is an important cause of cough, and therapy is available.[24,25,32] Interpreting the complaint is sometimes difficult because so many patients complain of "sinus" problems,[32] but in those with troublesome cough aggressive treatment of this syndrome may be worthwhile. Airway symptoms are often not fully appreciated. Patients may belittle their chronic sputum production or consider it normal, but sputum production is an important symptom of either chronic bronchitis or chronic rhinitis. Dyspnea, if present, is an important clue to a wide variety of cardiopulmonary disorders. Symptoms of esophageal disease such as heartburn or dysphagia should be looked for specifically.[13] Knowledge of underlying diseases, such as Sjögren's syndrome, which could affect drying of the mucosa, for example, may be very helpful.

Physical Examination

A thorough physical examination is clearly necessary to separate the many diseases that may cause cough. Irwin and co-workers found it useful 60% of the time.[21] If a patient does not cough spontaneously, ask for a voluntary cough and listen to the quality of the cough. The cough is "wet" in patients with asthma, bronchitis and postnasal drip and "dry" in those with most of the other conditions. Note if it is a deep chest cough or just clearing of the throat and if it is brought on by respiratory tract maneuvers during the physical examination, such as laughing or deep breathing. On examination of the ears, look specifically for irritating hairs or impacted cerumen. Polyps or bogginess of the nasal mucosa and visible mucus or cobblestoning of the oropharynx (an accumulation of lymphoid tissue that is common in children, but not normally seen in adults) may suggest chronic rhinitis. Other important clues on physical examination would include neck masses or fixation of the trachea, unsuspected crackles or wheezes, cardiac murmurs or gallops, midepigastric tenderness, clubbing or any signs of systemic illness.

Other Studies

Although we rely a great deal on chest roentgenograms for diagnosis, patients with chest diseases may on occasion have perfectly normal chest roentgenograms.[33] Of patients with interstitial lung disease, as many as 16% may have normal chest x-ray films.[33] Endobronchial neoplasm, particularly bronchial adenomas, bronchiectasis, cystic fibrosis, endobronchial tuberculosis and especially foreign bodies may not be radiologically detectable.[33]

Our approach to diagnosis begins with a data base that includes history, physical examination, chest film and spirometry. At this point, I would like to focus on what to do when a diagnosis has not been made by this basic approach. If there is sputum, it may be worth examining.[34] The finding of eosinophils may suggest asthma, whereas the finding of abundant polymorphonuclear leukocytes and bacterial organisms may suggest chronic bronchitis.

Formal pulmonary function studies including measurement of diffusing capacity and maximal expiratory flow-volume loops may be more sensitive than simple spirometry for early diagnosis of interstitial lung disease, chronic obstructive pulmonary disease and upper airway disease.[25] Though not yet widely available, bronchial stimulation with histamine or methacholine is an important way of identifying abnormal irritability or reactivity of the airways, as occurs in asthma.[23] About a quarter of the cases in the series of Irwin and associates were diagnosed by this technique.[21] The test measures abnormal responsiveness of bronchial smooth muscle as assessed by the increase in airway resistance or the decrease in the forced expiratory volume in one second (FEV_1) following inhalation of methacholine or histamine. This is a dose-related phenomenon, and people with asthma respond to much lower doses of inhaled drug than do healthy persons. Unfortunately, the test is not perfectly discriminatory as some patients, such as those with allergic rhinitis, may fall into the so-called asthmatic range.[23] Corrao and associates reported the cases of a small group of patients with chronic cough who had no history of dyspnea or wheezing, normal findings on physical examination and normal resting pulmonary functions.[35] When tested with inhaled methacholine, they all had a decrease in their FEV_1, whereas none of the controls responded in that way to the same dose. All six of these patients responded to bronchodilator therapy with resolution of their cough. When the drug regimen was subsequently discontinued, the cough returned. This is the most convincing evidence of the cough variant of asthma.

All of the other diagnostic studies are of less common use, and the decision to use them is initially based on the history. A patient with severe persistent cough, such as the one presented here, eventually will undergo most of them. The other studies that were done in this patient including exercise study, gallium scan and CT scan are certainly of much lower yield and are rarely used in the workup of a coughing patient. Psychiatric evaluation has a clear role after extensive medical evaluation.[22] It is especially helpful in an adolescent with psychogenic or habitual cough.[36] We have seen two teenagers with this dramatic syndrome. Both were shy, had school-adjustment problems and in both cases the cough bothered the parents much more than it bothered the children. As reported previously,[35] the critical historical feature was that even though the cough occurred every few seconds during the day, making school attendance impossible, it disappeared with sleep. The cough increased when either nurses or physicians were present. In the first case, the parents unfortunately signed the patient out of hospital when we suggested that there might be a psychogenic cause. In the second case, the patient returned home with our reassurance and instructions to the parents simply to ignore the cough and reassure the child that all would be well. One week after returning home to Florida, upon awaking one morning, she said to her mother, "I don't think I need to cough anymore."

Treatment

Not every patient needs such an extensive workup. If the history is clearly suggestive, response to empiric treatment may be an adequate "test." Specific therapy for most of the diagnoses mentioned is straightforward. A notable exception is postnasal drip or chronic rhinitis. A combination of topical nasal steroids (beclomethasone dipropionate or flunisolide), combined with one of the long-acting antihistamine decongestant combinations, may be dramatically effective.[37] If the cause is clearly allergic, topical administration of a nasal solution of cromolyn sodium may be successful. Cough-

variant asthma may be resistant to simple dilators but a course of corticosteroids may be required.[21]

Irwin's group looked at both the immediate and long-term results of treatment.[21] At the time of follow-up 1½ years after diagnosis, 10% of patients were still coughing. All but one of these had refused to continue their medication as they were content to know the cause of their cough and did not want to take drugs. Only one patient, whose diagnosis had been postnasal drip, was considered a long-term treatment failure.

There is a great deal of interest in the nonspecific treatment of cough and, in fact, there are more than 100 cough preparations listed in the United States Pharmacopeia. Reassurance may be the most important treatment, though sometimes it is difficult to give until a fairly extensive workup has been completed. If patients do experience mucosal dryness, humidification or expectorants may play a role, but there is not a single study that shows a convincing role for either.[38] Nonetheless, like most clinicians, I use these medications on occasion in the hope of easing expectoration. Much interest has focused on antitussives,[39-42] but there is almost no role for their use in the treatment of chronic cough. However, during the period of recovery following a viral infection, or when a patient has a clear cause of cough for which there is no further treatment, such as radiation-induced fibrosis, they may be very helpful. Codeine in a dose of 30 to 60 mg every six to eight hours is still the apparent drug of choice, though all narcotics are effective.[42] Administering dextromethorphan, a nonprescription narcotic derivative, is also quite efficacious though probably less so than giving codeine. Occasionally a patient, such as one we recently saw with radiation pneumonitis, may respond dramatically to oral benzonatate (Tessalon), 100 mg, three to four times a day.

Lidocaine inhaled from a nebulizer is an innovative approach to the treatment of cough. Unfortunately, reports of treatment of only several patients with chronic persistent cough are available.[43-45] We have tried it in a few patients at a dose of 200 mg (5 ml of 4% lidocaine), lower than the recommended dose of 400 mg. We have seen only temporary relief of cough (up to 48 hours)—not the several-week response reported elsewhere.[43-45] Another innovative approach of possible value is that of "airway rest," analogous to bowel rest for colitis. With this approach one attempts to interrupt the cough cycle with bed rest, cough suppression and sedation. Though an attractive idea, it has not been formally tested.

Conclusion

In conclusion, cough is an extraordinarily common reason for physician visits. Most coughs are related either to viral infections and are self-limited or are smoking-related. However, cough may be a cardinal and even disabling symptom of many diseases. The cause of persistent cough can usually be found by careful, if sometimes exasperatingly protracted, evaluation. Treatment is most effective when given for a specific diagnosis. However, even after the most extensive evaluation, some coughs will remain undiagnosed. In such cases, reassurance and symptomatic treatment are vital.

Questions and Answers

HOMER BOUSHEY, MD: *I wonder whether it is really helpful to diagnose as asthma the combination of cough and increased bronchial reactivity. The main point of measuring airway responsiveness is to identify which patients with cough may obtain relief from antiasthmatic medications. As for the patient you presented, I would like to know your actual thoughts as to the cause of cough. Do you think there are cough receptors in the distal esophagus, or do you think she was actually aspirating gastric acid?*

DR STULBARG: I know you have been interested in the role of gastric reflux in the development of asthma in some patients, so I am glad you brought this up. According to some reports, this occurs by aspiration,[46] but actual documentation that that is what occurs is limited.[47] Since you are our resident expert on bronchial reactivity, I would like to throw the question back in your lap. How do you think cough occurs in patients with esophagitis?

DR BOUSHEY: *We have been interested in this problem for some time and have examined the possibility of a reflex causing bronchoconstriction in six patients who had both asthma and esophageal reflux and who reported that their asthma worsened when heartburn developed. We instilled saline or diluted hydrochloric acid into the distal esophagus and measured airway resistance. Neither solution had a measurable effect, even when the symptoms of heartburn were provoked. These negative results in a few subjects do not, of course, exclude the possibility of such a reflex, but my own suspicion is that small amounts of gastric material are being aspirated.*

DR STULBARG: In defense of the concept of recurrent aspiration in this case, this woman did give a history compatible with repeated bouts of aspiration. She recalled many episodes of choking, occurring day and night, sometimes awakening her from sleep.

WARREN GOLD, MD:* *The research group here that is interested in airway function has been able to show even in asthmatic subjects that specific stimuli may cause cough without causing contraction of airway smooth muscle. The emphasis in your presentation that cough may often be a manifestation of asthma ought perhaps to be modified. In fact, people who present with intractable cough but without other airway stimuli in the environment may be different from patients with typical asthma.*

DR STULBARG: I think you are referring to the excellent research that has been done here on cough by Dean Sheppard and associates. It is known that inhaling distilled water has a very potent irritating effect on people with asthma and, in fact, will cause both cough and bronchoconstriction. The group here has shown that cough and bronchoconstriction can be separated.[48,49] It has generally been believed that the reason asthma causes cough is that the bronchoconstriction causes deformation of the irritant receptors, resulting in cough. The work done here shows that that is not always the case. When subjects inhaled a bronchodilator before inhaling the distilled water, the bronchoconstriction but not the cough was prevented. In a separate study they showed that if subjects inhaled lidocaine before inhaling the distilled water, the cough but not the bronchoconstriction was prevented. So these studies showed very clearly the separation of cough and

bronchoconstriction. How this relates to patients with cough and bronchial hyperreactivity, I am not sure.

Epitomes
Important Advances in Clinical Medicine

Dermatology

The Scientific Board of the California Medical Association presents the following inventory of items of progress in dermatology. Each item, in the judgment of a panel of knowledgeable physicians, has recently become reasonably firmly established, both as to scientific fact and important clinical significance. The items are presented in simple epitome and an authoritative reference, both to the item itself and to the subject as a whole, is generally given for those who may be unfamiliar with a particular item. The purpose is to assist busy practitioners, students, research workers or scholars to stay abreast of these items of progress in dermatology that have recently achieved a substantial degree of authoritative acceptance, whether in their own field of special interest or another.

The items of progress listed below were selected by the Advisory Panel to the Section on Dermatology of the California Medical Association and the summaries were prepared under its direction.

Chloracne

CHLORACNE IS A DISORDER of sebaceous follicles characterized by the development of a profusion of open and closed comedones and small, straw-colored cysts. These lesions are heavily concentrated on the malar aspect of the face, the postauricular region, the axillae, the groin and the extremities. The finding of squamous metaplasia of sebaceous glands on histopathologic examination may aid in distinguishing this condition from other acneiform diseases.

Chloracne is caused by the ingestion, inhalation or transcutaneous penetration of certain halogenated aromatic hydrocarbons. The ability to cause chloracne appears to be highly correlated with the systemic toxicity of these compounds. For example, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin is an extremely toxic molecule and is also a potent chloracnegen. In contrast, 1,2,3,4-tetrachlorodibenzo-*p*-dioxin, an isomer that differs only in the position of two chlorine atoms, lacks the ability to induce chloracne and is relatively nontoxic.

The evidence that the presence of chloracne is the single best and most sensitive indicator of exposure to certain halogenated aromatic hydrocarbons comes from the investigation of accidental human contamination. The chloracnegenic compounds are often unwanted by-products of the synthesis of such substances as herbicides (2,4,5-trichlorophenoxyacetic acid, a major component of herbicide Orange) and wood preservatives (pentachlorophenol), or they may directly contaminate foodstuffs (polyhalogenated biphenyls).

Chloracne will develop within three to four months in those persons exposed to a sufficient amount of a chloracnegenic chemical and generally will resolve within two years. Chloracne may persist after exposure to the inciting chemical possibly due to release of these substances from fat reservoirs. In rare cases the condition can continue for as long as 30 years.

In conclusion, the development of chloracne is the single most sensitive indicator of exposure to certain toxic polyhalogenated hydrocarbons. These substances appear to be inescapable by-products of modern industrialized society.

Recessive X-Linked Ichthyosis

RECESSIVE X-LINKED ICHTHYOSIS, an uncommon but not rare disorder, was clearly delineated from other genetic forms of ichthyosis through careful clinical and genealogic studies almost two decades ago. This form of ichthyosis is characterized clinically by the onset shortly after birth of closely adherent dark brown scales that most severely involve extensor surfaces of the extremities but also encroach on flexures. The trunk is involved as is the neck flexure; face, scalp, palms and soles are usually spared. Characteristic but asymptomatic opacities are present in Descemet's membrane of the cornea.

Although the prenatal syndrome of placental steroid sulfatase deficiency, characterized by extremely low maternal urinary estrogen levels despite fetal well-being, was first described in 1969, a decade elapsed before it was recognized that deficiency of this enzyme postnatally resulted in recessive X-linked ichthyosis. It has now been confirmed worldwide

that the microsomal enzyme, steroid sulfatase, is deficient in all patients with recessive X-linked ichthyosis.

Diagnosis of this disorder may be established by several methods. Prenatally, it can be inferred from a characteristic profile of maternal estrogen excretion and confirmed through direct enzyme assay in cultured fetal amniocytes. Postnatally, steroid sulfatase activity can be assayed in cultured fibroblasts or fresh leukocytes. The diagnosis can also be inferred from the accumulation of cholesterol sulfate, a substrate of the enzyme, in scale from these patients and in serum and erythrocyte membranes. In serum, cholesterol sulfate is carried on predominantly low-density lipoproteins (LDL); in cases of recessive X-linked ichthyosis, accumulation of cholesterol sulfate in LDL results in increased electronegativity of these particles—hence their altered electrophoretic mobility on lipoprotein electrophoresis. Thus, a readily available standard laboratory test may be used for the diagnosis of this disorder.

Other forms of ichthyosis have also been linked to abnormalities in epidermal lipid metabolism. This association is not surprising in view of the structure of stratum corneum, in which anucleated, keratinized corneocytes are surrounded by an extracellular matrix composed of neutral lipids (especially alkanes, triglycerides, free fatty acids, cholesterol and ceramides). Alterations in the composition of the extracellular lipid matrix affect the normal process of desquamation. Cholesterol sulfate, a highly amphipathic lipid, is one of the few remaining polar lipids in stratum corneum. Its hydrolytic enzyme, steroid sulfatase, also localizes to the intercellular regions of stratum corneum. Continuing hydrolysis of cholesterol sulfate as corneocytes move outward may be a critical factor leading to normal desquamation. In the stratum corneum of patients with recessive X-linked ichthyosis, absence of steroid sulfatase activity results in continued high levels of cholesterol sulfate, reduced levels of free sterol and impaired desquamation.

Subsets of Systemic Lupus Erythematosus

NEWLY DEFINED SUBSETS of lupus erythematosus are of value in defining prognosis and suggesting management approaches.

Subacute cutaneous lupus erythematosus is a cutaneous lupus variant characterized by mild systemic disease and slow therapeutic response. The lesions may be annular and polycyclic or papulosquamous and psoriasiform. Areas involved usually are the shoulders, upper chest and back. There is little scarring, photosensitivity is common and patients usually have mild systemic disease. Serologic markers of subacute cutaneous lupus include HLA-DR3 and the antibody anti-Ro (SSA [Sjögren's syndrome antibody]). In patients whose diagnosis is a problem, skin biopsy for hematoxylin-eosin stain and immunopathology should be done. In addition to the usual lupus serologic tests, studies for anti-Ro (SSA) antibody and HLA-DR3 may help to define the problem. It is important to differentiate the psoriasiform type from psoriasis, as therapy for psoriasis—that is, ultraviolet light—is contraindicated in patients with lupus.

Neonatal lupus erythematosus is a subset in which patients may or may not have cutaneous lesions. A "raccoon rash" is most common, though discoid and subacute cutaneous lupus lesions also occur. Mothers of these children may have clinical or serologic features of connective tissue disease. Systemic features of neonatal lupus include congenital heart block, hepatosplenomegaly and failure to thrive. Antinuclear antibodies are usually found, and the anti-Ro (SSA) antibody seems to be a marker in the patients and their mothers. The anti-Ro (SSA) antibody may be useful in prenatal screening of mothers with connective tissue disease and in identifying neonates at high risk for the development of congenital heart block.

Leukotrienes—Their Importance in Dermatology

THE LEUKOTRIENES CONSTITUTE a group of derivatives of arachidonic acid that were so named because they were first isolated from preparations of leukocytes and were all found to possess three conjugated double bonds. Neutrophils, macrophages, eosinophils, basophils and some populations of mast cells are capable of generating leukotrienes. Leukotrienes C_4, D_4 and E_4 (abbreviated LTC_4, LTD_4 and LTE_4) are unique among the known metabolites of arachidonic acid—which include the prostaglandins and thromboxanes—in respectively having the tripeptide glutathione, the dipeptide cysteinyl-glycine and cysteine alone, linked to the arachidonic acid skeleton. LTC_4 and LTD_4 constitute the major part of the activity that was previously called slow-reacting substance of anaphylaxis. In the skin, these two compounds cause increased permeability of postcapillary venules. Most significant, LTC_4 and LTD_4 are at least 1,000-fold more potent on a molar basis than is histamine. When injected into human skin, LTC_4 and LTD_4 produce classic urticaria, suggesting that these agents may be involved in the production of some types of urticaria, especially those that are unresponsive to antihistamine therapy. Unlike the prostaglandins and thromboxanes, the generation of leukotrienes is not suppressed by most nonsteroidal anti-inflammatory drugs such as aspirin, indomethacin or ibuprofen. However, corticosteroids do inhibit the generation of leukotrienes as well as the prostaglandins and thromboxanes.

Another leukotriene, designated LTB_4, which does not

incorporate a peptide or any amino acid into its structure, is an extremely potent chemoattractant for neutrophils. When placed on human skin, LTB_4 will induce the influx of neutrophils into the epidermis and dermis. Of clinical interest is the observation that there are elevated levels of LTB_4 in the lesions of psoriasis that are characterized in part by their dense infiltrate of neutrophils. Because the neutrophil is a rich source of LTB_4, it is as yet unclear whether the elevated levels of this leukotriene in psoriatic skin are purely the result of the presence of the neutrophils or whether the skin is itself generating this chemoattractant. In this context, it should be mentioned that another arachidonic acid metabolite called 12-hydroxyeicosatetraenoic acid (12-HETE) is generated by isolated epidermal cells, is 80-fold to 100-fold elevated in psoriatic lesions and, like LTB_4, can cause the influx of neutrophils into human skin. Thus, this agent may be initially responsible for attracting neutrophils into the psoriatic skin, and these neutrophils, through their release of LTB_4, then attract more neutrophils. Such proposed pathogenic mechanisms have yet to be clearly established. However, both the presence and the biologic potency of the leukotrienes in human skin provide very strong justification for research that will address the possible roles in cutaneous disease of these relatively recently isolated lipid and peptidolipid mediators.

Bovine Injectable Collagen

BOVINE INJECTABLE COLLAGEN (Zyderm Collagen Implant) has been approved by the Food and Drug Administration as a xenogeneic device available for soft tissue augmentation. It is used to correct small distensible cosmetic defects such as disease- or trauma-induced atrophy, postcosmetic surgical abnormalities, shallow acne scars and age-related wrinkles. It is not appropriate, for example, for correcting ice-pick scars or facial hemiatrophy.

The material is produced from bovine dermis that has been subjected to pepsin hydrolysis to cleave the more antigeneic telopeptides and make its implantation more immunologically acceptable to the human host. The resultant product is dispersed in saline solution containing 0.3% lidocaine and is available in two concentrations: 35% by volume of collagen (Zyderm I) and 65% by volume (Zyderm II).

Treatment with injectable collagen requires an initial screening skin test. Approximately 0.1 ml of the material is placed intradermally in the volar area of the forearm and the site evaluated over one month. A positive test consists of redness, swelling or both after six hours and contraindicates treatment. About 3% of persons will have a positive skin test. Nevertheless, despite one negative skin test, 1.3% to 6.2% of patients will have treatment-associated reactions of swelling and redness at the treatment site. These treatment reactions usually last four to six months and occasionally longer. To reduce the possibility of these reactions a second skin test a month after the first can be administered in a cosmetically inconspicuous area of the face and the treatment begun two to four weeks after a negative second test. Also, if a patient has not been tested or treated within a 12-month period, it is advisable to retest once to reduce the possibility of a treatment reaction.

Correction of defects requires two to three treatment sessions at two- to four-week intervals. At these visits the Zyderm collagen is implanted in the superficial papillary dermis by serial punctures of the skin with syringes prefilled with the material. In implanting the substance, one must deliberately overcorrect and observe a blanching of the skin with wheal formation at the injection site. Correction with collagen is temporary and requires periodic maintenance at 6- to 12-month intervals.

Treatment reactions to collagen are, for the most part, cosmetic and consist of redness and swelling at the treatment sites; mild systemic symptoms are, rarely, associated with these reactions. The only serious sequela is one case—out of more than 100,000 treated persons—of unilateral loss of vision due to probable inadvertent intraarteriolar injection. Treatment-associated reactions are almost uniformly associated with anti-Zyderm antibodies that do not cross-react with human collagen. Though patients with collagen vascular disease are excluded from therapy, the fear that injectable collagen would induce collagen disease has been shown to be unfounded in its eight years of use.

Presently, studies are underway utilizing bovine injectable collagen in other than cosmetic areas such as cases of esophageal reflux, laryngeal paralysis, bone grafting, urinary incontinence and corns and calluses. A more robust form of collagen that is longer lasting and of value in larger cosmetic defects is being evaluated.

To date, the considerable experience with injectable collagen attests to its safety and efficacy. Nevertheless, only future studies will define its ultimate role in the cosmetic and noncosmetic medical armamentarium.

The Diabetic Hand Syndrome

SEVERAL RECENT OBSERVATIONS SUGGEST that a thickened dermis and limited joint mobility of the fingers may be a common finding in patients with diabetes mellitus. Painful, stiff hands were described as an uncommon complication of insulin-dependent diabetes mellitus as early as 1957. Subsequent descriptions of this syndrome in 1978 and 1980 showed that this phenomenon is a rather common finding in children with diabetes mellitus. About a third of children with diabetes have been noted to have limited joint mobility of the hands and

a third of these have thickened skin on the dorsum of the fingers and hands. Most recently, it has been observed that limited joint mobility of the hands is also a common finding in adults who have diabetes mellitus.

Does this new finding have any significance in regard to other parameters of diabetes? Most reports suggest a correlation of these hand findings with diabetic retinopathy. It has also been suggested that this dermal thickening is the result of glycosylation of collagen, which results in a relative resistance of collagen to collagenase and a stiffer, stronger collagen. Increased glycosylation of collagen and the resulting changes in the biomechanical properties of this molecule occur normally with aging, and the occurrence in patients with diabetes is consistent with accelerated aging. Reports on the correlation of the diabetic hand with control of diabetes have, however, been conflicting.

In summary, skin and joint changes of the hands are fairly common findings in patients with diabetes mellitus. Along with other prognostic indicators, these changes should be sought on physical examination of diabetic patients. Although it is tantalizing to consider that hyperglycemia resulting in collagen glycosylation may be responsible for both dermal thickening and internal complications of diabetes mellitus, such a connection is far from proved. For clinicians today, the diabetic hand syndrome remains a relatively common and interesting finding that has a probable correlation with retinopathy.

Malignant Melanoma—Recognition of New Histologic Variants With Favorable Prognosis

SINCE THE ORIGINAL WORK on ocular melanoma showed that patients with nonpigmented spindle cell melanomas have a better prognosis than those with other types, several studies have been done to determine which clinical and histologic variables have prognostic significance for primary cutaneous melanoma.

Results of these studies have uniformly indicated thickness to be a major prognostic indicator, but data regarding the significance of other histologic features remain less than clear, in part because of differences between studies and in part because some studies were based on the premise that lentigo maligna melanoma has a better prognosis than superficial spreading melanoma, which has a better prognosis than nodular melanoma. Therefore, cell types most often seen in patients with lentigo maligna melanoma were inferred to indicate a better prognosis.

In a recent study by Koh and co-workers, of 48 cases of lentigo maligna melanoma matched with non-lentigo maligna melanoma for site and thickness, a Cox multivariate analysis selected only thickness in predicting death. As with other large multicenter cooperative studies, this study indicated little or no independent impact of histologic features on the prognosis of patients with clinical stage I melanoma (primary melanoma with no clinical evidence of metastasis).

Histologically, lentigo maligna melanoma and superficial spreading melanoma are characterized by a radial growth phase or the horizontal spreading of malignant cells within and just beneath the epidermis (Breslow's level less than 0.76 mm or Clark's level I and II, indicating a good prognosis). In time, a vertical growth phase supervenes, expanding to more than 1.25 mm or Clark's level III, IV or V, indicating an increasingly worse prognosis. In nodular melanoma a vertically expanding nodule is characteristic and the radial growth phase may not be recognizable.

There is a histologic variant of malignant melanoma called minimal deviation melanoma that may prove to be the exception to the rule. This uncommon nevomelanocytic tumor appears clinically as a Spitz nevus, hemangioma or malignant melanoma. They occur on any body site, at any age and may arise in preexisting dermal nevi or in the midst of a congenital nevus. Histologically, cells making up an expansile nodule of the vertical growth component show mitotic figures but very minimal cytologic atypism such that, if the nodule arises in a nevus, differentiation of malignant from benign cells may be very difficult. When the nodule is located within Clark's level II, the lesion is called a borderline minimal deviation melanoma, borderline indicating the biologically benign nature of the lesion unless it penetrates to level III where its biologic behavior is unpredictable. (Other melanomas would predictably have a progressively worse prognosis).

Muhlbauer and colleagues recently reported a study of 21 patients with minimal deviation melanoma. The mean tumor thickness was 3.6 mm, or level V. After 57 months, only two of three deaths could be attributed to melanoma, the other patients being disease free.

Because of the less aggressive nature of these lesions, the authors express hesitation at assigning a Breslow or Clark's level because of therapeutic implications (local excision versus wide excision with possible lymph node dissection).

A Micrographically Controlled Operation for Difficult Skin Cancers

ABOUT 40 YEARS AGO, Mohs developed a technique to remove skin cancers that has been modified to obtain a fresh tissue specimen for microscopic examination with careful mapping, now called micrographically controlled surgery.

Skin cancer accounts for 25% of all cancers in humans,

the most common of which are basal cell carcinomas that occur on sun-exposed areas of the head and neck. Persons with fair skin living in lower latitudes are at increased risk for the development of skin cancer. The incidence of skin cancer doubles for each 3°45′ of latitude toward the equator. Treatment includes curettage and electrodesiccation, excision, irradiation, cryosurgery and micrographically controlled surgical excision of tumors with high recurrence rates.

Technique

The micrographically controlled operation is done under local or regional anesthesia. The tumor is debulked. The specially angled saucerized tissue specimen is cut horizontally across the bottom in serial frozen sections. The entire undersurface and the epidermal margin of the excised tissue can be seen microscopically and mapped. One is then able to remove only tissue in which the tumor is microscopically persistent, allowing maximal preservation of normal skin. Mohs's surgical procedure is used for certain primary basal cell carcinomas and squamous cell carcinomas, most recurrent skin cancer, verrucous carcinoma and other paracutaneous neoplasms in the mouth and sinuses.

The criteria for selecting Mohs's procedure over other modalities in treating cases of primary basal cell carcinoma include tumor location, histologic analysis, size (greater than 2 cm) and clinical characteristics. In cases of recurrent basal cell carcinoma, a micrographically controlled surgical procedure is clearly the treatment of choice. The criteria are comparable for the less frequently occurring squamous cell carcinomas.

Tumor location is important. Areas of high recurrence are embryonic planes including the nasal septum, the nasal ala, the junction of the nasal ala with the nasolabial fold, the periorbital region and the periauricular region extending to the temple. Basal cell carcinoma follows the paths of least resistance, along facial planes, periosteum, perichondrium and eyelid tarsal plate, spreading along these structures before invading.

Primary basal cell carcinomas have several histopathologic characteristics with differing biologic behavior. Morpheaform or sclerotic basal cell carcinomas, multicentric infiltrating tumor or the keratinizing aggressive basal cell carcinoma (metatypical carcinoma) can be clinically aggressive with higher recurrence rates than nodular basal cell carcinomas. Sclerotic basal cell carcinoma can have a large subclinical extension, especially on the temple and forehead.

A third factor is tumor size. For tumors larger than 2 cm, Mohs's operation is generally recommended. The cure rate for Mohs's procedure is 98.6% for tumors between 2 cm and 3 cm in diameter and 90% for tumors greater than 3 cm in diameter. Most basal cell carcinomas are well-defined nodules. However, some have ill-defined clinical borders exhibiting a multicentric nature. In this situation Mohs's operation might be considered a treatment of choice if a large, clinically judged excision is not appropriate.

Incompletely excised basal cell carcinomas have variable recurrence rates: 82% on eyes, ears and nose and 25% on the remainder of the head and neck. Mohs's surgical procedure has a success rate of about 96% for recurrent basal cell carcinomas compared with the 50% success rate of other modalities. It has the additional advantage of preserving the maximal amount of normal skin.

In conclusion, location, histologic characteristics, size and clinical nature of a primary skin cancer are important in deciding the most effective treatment modality.

New techniques to improve the cure rate are immunofluorescent and immunoperoxidase staining antibodies to keratin. This keratin antibody staining in frozen section appears to be an effective method of distinguishing strands of cancer cells in poorly differentiated squamous cell carcinoma or morpheaform basal cell carcinoma from inflammatory cells.

Minoxidil

MINOXIDIL IS a potent peripheral vasodilator used in treating patients with hypertension. When taken orally, the drug causes a reversible, nonvirilizing hypertrichosis in most patients. In women, the increased hair growth involves the face, shoulders and limbs and, in men, there is a generalized increase of body hair.

Topical minoxidil, not yet approved by the Food and Drug Administration, is being studied in large, multicenter projects to assess the drug's efficacy and safety when applied to the scalp of patients with alopecia areata and those with androgenetic alopecia.

In men, women and children with alopecia areata affecting 25% to 99% of the scalp, topical application of minoxidil produces hair growth in about 30% of the patients after a year of treatment. The results with 1% and 3% topical minoxidil are similar. After two and three years of topical treatment, it is possible that a higher percentage of patients, including some with 100% scalp hair loss, will grow cosmetically acceptable hair. One study has shown a substantially greater response rate using 5% minoxidil in cases of alopecia areata.

In men with androgenetic alopecia, cosmetically acceptable hair growth is achieved in about 30% after twice-a-day application of minoxidil for one year. Both 2% and 3% topical minoxidil produces similar results in patients with androgenetic alopecia. Hair growth begins after four to six months of treatment. The presence of pigmented hairs longer than 1 cm is a favorable indicator for response; the greater the density of such miniaturized hairs, the more likely the patient will respond well to topical application of minoxidil. In addition, the shorter the duration of the balding process and the smaller the balding area, the better the likelihood of a cosmetically acceptable response.

Topical minoxidil appears to be safe in those with a normal cardiovascular state. Side effects have consisted mainly of mild skin irritation in only a few patients.

The mechanism by which minoxidil stimulates hair growth in patients with alopecia areata and androgenetic alopecia is unknown and it is the first drug to grow hair in both of these unrelated conditions. Many questions remain to be answered. The optimal concentration, the frequency of application and the duration of therapy all must still be determined.

Topical minoxidil is a promising new drug for stimulating hair growth in patients with alopecia areata and androgenetic alopecia. Those using it must understand that it works very slowly, treatment is necessary for at least one to three years, perhaps longer, and the hair regrowth may not persist after treatment is stopped.

WJM Welcomes Arizona and Montana

The Arizona Medical Association and the Montana Medical Association have each voted to join the *WJM* family of sponsoring state medical societies. They join the medical associations of California, Idaho, Nevada, New Mexico, Utah, Washington and Wyoming (as well as six research and specialty societies) in designating *WJM* as their official scientific journal. The editors and staff of *WJM* welcome them and look forward to many years of shared endeavor.

The monthly circulation of *WJM* will now be something more than 53,000. It is worth noting that the subscribers and readers extend far beyond the boundaries of the western medical associations and societies that officially sponsor the journal. There are paid subscribers in every state of the union and most foreign countries. Reprint requests during the last year for the Epitomes section alone (the only section for which we are able to monitor this) have been received from Australia, Belgium, Bulgaria, Canada, Cuba, Czechoslovakia, East Germany, Ecuador, Estonia, France, Israel, Italy, Mexico, Nigeria, Poland, Romania, Spain, Venezuela and West Germany.

So it is clear that as the journal has been developing its strong base among the western states, it has not only been serving the members of its family of state medical associations and other affiliated societies, but has also begun to extend the influence of medicine in the West to the rest of the nation and to many far away parts of the world.

The Mind, the Brain and Ulcer Disease

Peptic ulcer disease in humans results from an imbalance between aggressive forces—acid and the proteolytic enzyme pepsin—and the endogenous defense mechanisms, which may include mucus and bicarbonate secretion, the maintenance of adequate mucosal blood flow and the inherent ability of the epithelium to maintain its integrity in the face of a large proton gradient. Since the range of acid-pepsin secretion is wide and most duodenal ulcer patients fall within the normal limits, the implication is that impaired mucosal resistance is the primary factor in ulcer formation. These defensive mechanisms are apparently influenced by both genetic and environmental factors, but quantitative assessment of these factors is not yet possible.

To perceive disease formation as the result of a simple imbalance of two opposing forces is of course reasonable, but simplistic. It would be equally simplistic to assume that an interruption of an intercontinental telephone conversation occurred because the plug was pulled on one of the telephones involved. Although it may be the case, the problem may well exist anywhere in the myriad of switches and computers that permit the conversation to occur.

In the symposium "Neurobiologic and Psychobiologic Mechanisms in Gastric Function and Ulceration" published in this issue of the journal, a group of scientists representing multiple disciplines review the data available on this subject. Although the symposium is scholarly in its scope, one is left with a sense of confusion, not from the presentation specifically, but from the unease one senses when confronted with many pieces of a gigantic, complex puzzle not yet organized.

Several questions contribute to this complexity. Are these experimental animal models relevant to human function and disease? Can the interspecies variations (cat, dog, rat) be reduced sufficiently to permit adequate conclusions? Can any of the numerous mechanisms noted in the symposium—the neural pathways, mechanoreceptors, chemoreceptors, osmoreceptors in the gastrointestinal tract and the liver and neuropeptides in the brain and gut—be shown to be physiologically relevant and not just demonstrable phenomena elicited in the experimental setting? Furthermore, to fully understand the mechanisms that control both feeding behavior and gastric function in humans, should we not search for the integrative links among (1) experience, that which occurs from the environment; (2) internal conflict—that is, unconscious processes of the mind—and (3) the neurophysiology?

As the discussants describe, the amygdalar structure within the limbic system has been implicated in emotionality and responsivity to stress. Neural connections between the central nucleus of the amygdala and the lateral hypothalamic area have been documented in rats.[1] Electrolytic lesions of the centromedial amygdaloid area result in marked alteration of gastric acid secretion. The lateral hypothalamus has, in addition to its connections with the limbic system, connections with the autonomic nervous system. The nature of these connections, however, is still unclear. The lateral hypothalamic area in various species has been shown to be clearly involved in the regulation of gastrointestinal function. Therefore, the evidence suggests that there is demonstrable "machinery" that may control gastrointestinal function existing well within the physical confines of the brain. In addition, in the symposium, Novin states that there "seems to be good evidence that the entire upper alimentary canal, the liver and the brain provide input important in feeding regulation." However, he goes on, "none are necessary components of that regulation," strongly suggesting "a redundant system of multiple inputs." Presumably, the brain integrates the diverse information "in a hierarchical organization," with increasingly complex afferent input and integration probably requiring higher levels of the nervous system.

However, it is not yet established how the *mind*—the anatomically elusive mental apparatus that is the source of both conscious and unconscious psychic processes—interacts with the physical system described in the symposium. What is the role of the mind in regard to gastric function and ulcer formation? There is some evidence that the mind does influence the rate of acid secretion and the motility of the stomach, but it is not yet established that this relationship is important in the cause of ulcer disease. Psychological stress has been considered to have an important role in either the genesis or exacerbation of ulcer disease. Here again, the evidence has been

suggestive but inconclusive.[2] A recent report about two men who experienced extraordinarily stressful life events lends support to the hypothesis that psychological strain can result in actual ulcer disease.[3] Ulcer symptoms in one began soon after he experienced the death of six family members in a six-week period and feared his own death. In the second case, symptoms followed his being accused of grand theft, being under police surveillance and losing his job. Both patients had greatly increased gastric acid secretion rates that decreased to normal after admission to hospital and reassurance in the first case and acquittal in the second. But by what mechanisms do these and other experiences translate into disease?

The literature on the subject since the 1930s has concentrated on the presence of excessive dependency needs in patients with duodenal ulcer disease, and recent preliminary data, in fact, suggest that peptic ulcer disease patients are more dependent than age-matched control subjects.[4] Following psychoanalytic theory and data from unconscious material obtained from ulcer patients given the Thematic Apperception Test, one might suggest the following: the young infant, perhaps genetically vulnerable, experiences real or fantasized loss, perceived as the absence of or inadequate fulfillment of the need to be soothed via adequate feeding. The wish to be fed is associated with a cephalic phase response of gastric acid secretion. Later in life, this adult who has become excessively dependent suffers a real or threatened loss, reacts with a sense of helplessness and regresses to the "oral phase" where the association between loss and acid secretion occurs. However tempting this scenario might be, it must be noted that it still does not pinpoint the elusive link between the psychological process and the brain function discussed in the symposium. Furthermore, the fact that ulcer disease may be caused or exacerbated by such a dependency "trait" does not necessarily imply that adults with the trait are automatically predisposed to peptic ulcer disease. In view of the recent recognition of the concept of heterogeneity in medical disorders, especially clear in peptic ulcer disease, it is no longer necessary to explain all cases of any disease with the same pathophysiologic description.[5] Therefore, it is theoretically possible that psychological factors may be relevant in one subgroup and not in another. There may be many routes to the eventual hole in the gastroduodenal mucosa, and our puzzle remains unsolved with only a few scattered links here and there.

Sigmund Freud apparently thought that this search to discover a specific neurochemical link between psyche and soma was a fruitless venture. In the last account of his ideas, Freud acknowledges the presence of both the bodily organ (the brain) and the mental apparatus with its conscious and unconscious components (the mind). Regarding the interaction of mind and brain, he wrote, "Everything that lies between is unkown to us, and the data do not include any direct relation between these two terminal points of our knowledge."[6]

Although the void in our understanding of the mind and brain has seemed unbridgeable, one must wonder if new diagnostic techniques such as positron-emission tomography will elucidate cortical functions not yet appreciated[7] or whether we will continue to label and identify parts without understanding their true relationships.

These problematic questions and the enormous data pool already accumulated should not discourage us, but rather, as so often seems the case in scientific investigation, act as a catalyst for more specific questions that will permit clarification and hopefully a substantial furthering of our knowledge.

Biological and Societal Interdependence

IF ONE READS CAREFULLY the specialty conference on gastric function and ulceration that appears elsewhere in this issue, one is impressed by the as yet poorly understood interrelationships and indeed interdependence among the biologic processes discussed. If one has been a more or less regular reader of these columns, one may have noted that this writer has often reflected on the poorly understood relationships and indeed interdependence among the social, economic and political pressures in today's very human and very technologic society. And a reader may also have discerned that this writer sees a link between biological and societal interdependence with biologic connotations that are also as yet poorly understood.

In both biology (whether human or not) and human society one senses dynamic and ever-changing relationships where many things are going on at once, each affecting and being affected by all the others. Deductive science with its linear approach, in which most of us have been trained, does not now seem adequate to deal with the merging dimensions of biological and societal interdependence. New methods and new approaches should be sought. If these can be developed in biology and human medicine, then medicine could become the basic biologic and social science to develop a better understanding of the human and societal interdependence which is so much a reality in the world today. This could be a major challenge of the times.

Water Distribution and Oxygen Delivery

. . . Too much water hast thou, poor Ophelia.

WILLIAM SHAKESPEARE
Hamlet

WATER HAS DEFINED geographic boundaries and separated national and cultural groups throughout the ages; moreover, water rights have been a source of endless human conflict. It is not surprising, therefore, that strongly held views on the problems of body water distribution and fluid management have separated physicians and, indeed, the various medical specialties. Internists most often are confronted with edema-

tous patients in cardiac, renal and respiratory failure; to a large extent, these patients require diuretics with water and salt restriction. On the other hand, surgeons who should know more about shock from having caused much of it are alleged to flood their patients with too much salt and water. Elsewhere in this issue, Waxman and associates have critically reviewed the problems of fluid therapy with blood and plasma substitutes, emphasizing oxygen transport properties. They wisely dismiss crystalloid solutions which, though cheap, are inefficient plasma expanders because they are preponderantly distributed in the interstitial space; only a relatively small proportion (less than 20%) is left in the plasma volume at the end of the infusion and this subsequently disappears from the plasma volume exponentially.[1]

A major neglected problem is the pronounced redistribution of water that commonly occurs with shock, trauma and critical illness, namely, expanded interstitial water in spite of hypovolemia.[2] This occurs despite the frequent claims of the crystalloid proponents that if you give enough crystalloids, the plasma volume eventually will be restored. To do this, Lucas and colleagues[3,4] give 30,000 ml more of fluids than are lost in the urine and they require a 25-kg weight gain; they found an exceedingly high percentage of their resuscitated patients required digitalis. This position is somewhat reminiscent of the used-car salesman who claimed he lost money on every sale, but made up for it by the volume, or of Hamlet who discovered his beloved face down in the brook.

Waxman and co-workers expertly summarize the physical properties of dextran, hydroxyethyl starch, perfluorochemicals and stroma-free hemoglobin. The latter is not approved by the Food and Drug Administration (FDA), and Fluosol DA, which was the only perfluorochemical that underwent FDA testing, was withdrawn after unsuccessful clinical trials. These investigators have evaluated the physical capacities of the two new agents that are of great theoretical interest because they are able to bind and carry oxygen, even though they are not yet clinically available. Administration of 1,000 ml of Fluosol DA 20% increases the arterial oxygen content 2.3 ml per dl in cases of severe anemia.[5] This is equivalent to the amount produced by about 1½ units of packed erythrocytes.

Possibly of greater usefulness than the physical properties of presently unavailable agents are the physiologic capacities of presently available agents to affect oxygen transport and metabolism in a disturbed circulation. The oxygen content of arterial blood in vitro is less important than oxygen delivery to the tissues in vivo because agents that draw more water into the plasma volume increase proportionately the cardiac output and may deliver more oxygen than the agent that merely contains more oxygen. It might be more appropriate to describe the immediate direct physiologic effects of whole blood transfusion or its components—packed erythrocytes, albumin and plasma protein fractions.[5-9] This is necessary to develop a "gold standard" with natural fluids against which the relative efficacy of various synthetic agents may be assessed under various clinical circumstances. Available data show that (1) in normal preillness conditions one unit of whole blood produces small but significant increases in cardiac index and oxygen delivery but little or no improvement in oxygen consumption; (2) in postoperative conditions, one unit of whole blood increases cardiac index an average of 0.44 $\pm$ 0.10 (standard error of the mean) liters per minute per m^2 mean arterial pressure 9 $\pm$ 3 mm of mercury, comparable increases in the derived hemodynamic variables, oxygen delivery of 87 $\pm$ 27 ml per minute per m^2 and oxygen consumption of 24 $\pm$ 8 ml per minute per m^2; (3) in patients with early postoperative shock, acute respiratory failure and sepsis, administering 500 ml of whole blood or plasma expanders produces greater increases in cardiac index, oxygen delivery and oxygen consumption than under normal preoperative control conditions; (4) in general, administering 250 ml or 500 ml of plasma expanders produces greater hemodynamic and oxygen transport effects than does giving 1,000 ml of saline, and (5) in the terminal state there is very little improvement in any of the hemodynamic and oxygen transport variables after transfusions of plasma expanders.[5-10] Thus, in the early stages of shock and critical illness, the various natural and synthetic colloids expand the plasma volume more than the infused volume,[1,9] but in the late stages of shock, capillary leak or maldistribution of body water (or both) limits their effectiveness.[1]

Matsuda and co-workers[6] observed that the physiologic responses of administering 500 ml of dextran 40 varied widely depending on the underlying state of the patient. Similarly, McCartney and Appel compared the relative effectiveness of the use of hydroxyethyl starch in normal persons, patients before, during and after an operation, patients with sepsis, elderly persons, patients with cirrhosis and those with respiratory failure (S. F. McCartney, MD, and P. L. Appel, MPA, written communication, February 1984). In essence, the physiologic effects of blood, plasma components and synthetic plasma expanders are dependent on the blood volume deficit, the peripheral circulatory defect, the etiologic basis of the disturbed circulation, the duration of the shock state and the reserve capacity of the heart, lungs and other organs.

The therapeutic objective in a critically ill patient is not to restore cardiac function to a normal state but rather to restore the oxygen transport functions of the circulation to their optimal values defined empirically by the values of survivors of life-threatening critical illness, because these values are related to, and may indeed be determinants of, survival.[11] To accomplish this it is necessary to mix and match the physiologic defects that a patient has with the physiologic effects of available therapeutic agents. This is not properly done on theoretical grounds based on in vitro physical properties, but by empirical in vivo measurements of the relative physiologic effectiveness of each of the various agents under each of the various clinical conditions. In essence, the empirical trial of therapy under specific conditions as advocated by Hippocrates provides objective evidence for clinical decision making. An agent is not necessarily inherently good or bad, but rather more or less appropriate than another agent according to its physiologic effects in a given clinical condition.

The Importance of Caring

MUCH IS BEING WRITTEN these days, and much is being said, about the caring function of physicians. It well may be that where there is this much smoke there may be some fire. Perhaps it is time for physicians and the profession as a whole to devote more time and attention to the caring part of patient care. There is reason to believe that too often this may be something taken for granted by physicians, but not so much so by patients or by society. In fact there already may be some significant social, economic and political fallout from the perception that physicians and the profession are caring less—or the reality of it.

Caring is a very human and very personal matter. It is not particularly scientific although science and technology can be used as tools for caring. One can care for things—a well-restored vintage automobile, for example—but in medicine and medical practice the caring must be for patients and for the health and well-being of people. To be effective, caring must be communicated and come across to a patient or to the public as something genuine and comforting—something that can engender trust. When developed and used effectively—that is, communicated—caring can become a powerful therapeutic tool for a practicing physician and, perhaps surprisingly, an effective political tool for the medical profession. Nobody wants a doctor or a health care system or a medical profession that doesn't care.

Yet there is evidence that caring is not now the powerful force that it has been and can be in medicine. The beloved horse-and-buggy doctor cared and gave solace and comfort. True, there often was not much else he could do, but the caring was appreciated and society thought well of the horse-and-buggy doctor. Now physicians can do more with modern science and technology than has ever before been possible, and many are so fascinated by this that they become so preoccupied by the scientific diagnosis and the scientific treatment of a disease that they seem too often to neglect the care and treatment of the very human person who has the disease. The human caring communication between doctor and patient or between the medical profession and society is apt to receive short shrift, or is simply overlooked entirely. Nor has the compartmentalization of medicine into specialties and subspecialties done much to help, since a result has been compartmentalization in patient care and, therefore, less emphasis on the less scientific needs of the whole person who may be affected in many ways by the trouble in one or more of his or her compartmentalized parts. And now, what is left of caring seems to be threatened by new pressures in health care that are beginning to drive significant economic wedges between doctors and patients, wedges that some think will surely erode and perhaps finally altogether destroy a physician's incentive for caring.

There is already evidence of economic and political fallout from these trends which seem to have been accelerating so rapidly in recent years. Many patients have begun to sense that the care of physicians is less than satisfying to them and have sought care (and caring) elsewhere. This clearly has had and is having economic impact on physicians. And in the political arena there is mounting evidence of significant progress by other health care professionals to extend their scope of practice in response to what is perceived as a growing demand for their services. There has been surprisingly little interest among practicing physicians or in the medical profession as a whole either in identifying the cause or effecting a cure for what already seems to be a serious ailment in modern medicine and modern medical practice.

But perhaps it is not too late. There are soon to be many more physicians and many of them will have more time on their hands, time that it will be to their economic advantage to use for caring and communicating—with patients and the public. And it is not to be forgotten that the desire to care for people, as well as their ailments, is why most physicians decided to become doctors in the first place. What is needed now is for practicing physicians and the medical profession to resurrect the human and caring aspects of their great calling, bring them to the fore, and make medical science and technology, and the social, economic and political forces that are so evident today, their servants in this cause and not let them be the masters. This can and should now become a personal commitment of every physician and an organizational commitment of the profession. It may well be that the power inherent in the caring function can serve physicians as well now as it has in the past. After all, the real and ultimate social, economic and political power in this nation still lies in the hands of the people—people who nearly all will somehow have their lives affected by physicians.

Case Reports

Pseudofractures in Patients With Low-Turnover Osteoporosis

ERIC S. ORWOLL, MD
MICHAEL R. McCLUNG, MD
Portland

PSEUDOFRACTURES (Looser's zones, Milkman's fractures) were first described in Germany and Austria in the period immediately following World War I.[1-3] Their cause was considered to be lack of adequate nutrition (hunger osteopathy) and many of the cases initially reported to have this radiographic finding had evidence of osteomalacia or rickets. In 1930 Milkman described the first case of pseudofractures in the English literature.[4] They are characteristically linear, radiolucent areas, frequently with sclerotic margins, that most commonly occur perpendicular to the periosteal surface in ribs, scapulae, the pelvis and long bones. Their presence has proved to be a useful roentgenographic sign of osteomalacia. In fact, recent reviews of osteomalacia have emphasized the diagnostic value of pseudofractures and have reasserted that pseudofractures are a pathognomonic sign of that disorder.[5,6] We report, however, two patients in whom multiple, symmetric pseudofractures occurred in the presence of low-turnover osteoporosis and in the absence of any evidence of osteomalacia.

Reports of Cases

Case 1

The patient, a 73-year-old woman, was referred to the Bone and Mineral Clinic at The Oregon Health Sciences University for evaluation of osteopenia presumed to be due to osteomalacia. A year earlier she had the onset of sharp or aching bilateral inguinal pain that was considerably worsened with weight bearing or hip movement. After several months of gradually increasing discomfort, she sought treatment from a chiropractor who "manipulated" her pelvis. These manipulations were carried out periodically over a six-month period but the discomfort continued and she was finally confined to a wheelchair. She saw a physician and a radiograph showed pseudofractures in all four pelvic rami (Figure 1). A technetium Tc 99m diphosphonate bone scan showed increased uptake in those areas but was otherwise unremarkable.

The patient said she had had no previous bone disease, rickets, bone tenderness, back pain, diarrhea, weight loss, operations, alcohol use or renal disease. The patient's only medications were six tablespoons per day of Maalox or Mylanta for esophageal reflux (two years) and one multivitamin per day that contained 400 IU of ergocalciferol (two months). She had received a two-month course of estrogen therapy that had been discontinued five years before.

On physical examination she was mildly obese and had mild dorsal kyphosis without vertebral tenderness or scoliosis. There was minimal tibial and clavicular tenderness and slight generalized weakness. An initial laboratory evaluation elicited the following values: serum creatinine, 1.0, calcium, 9.6, and phosphorus, 3.5 mg per dl; total protein, 7.4 grams per dl; alkaline phosphatase, 118 mU per ml (normal, 35 to 105). Serum aspartate aminotransferase (AST, formerly glutamic-oxaloacetic transaminase) and bilirubin concentrations were normal. Serum 25-hydroxycholecalciferol level was 36 ng per ml (normal, 10 to 50) and serum 1,25-dihydroxycholecalciferol (1,25-dihydroxyvitamin D_3) concentration was 53 pg per ml (normal 30 to 75). Fasting urinary adenosine 3′:5′-cyclic phosphate concentration was 3.4 nmol per dl glomerular filtration rate (normal, 1.8 to 4.5) and 24-hour urine calcium excretion was 114 mg while on a routine diet.

Radiographs of the lumbosacral spine showed osteopenia with anterior wedge fractures of L-2 and L-3. Single-photon absorptiometry done at the junction of the distal and middle thirds of the radius showed a bone mineral content of 0.64 grams, bone width of 1.2 cm and bone mineral content/bone width of 0.53 grams per cm^2 (normal for age and sex, 0.57 ± 0.085 standard deviation [SD]). At the distal radial site (2 cm proximal to the ulnar styloid), the bone mineral content was 0.7 grams, bone width 2.5 cm and bone mineral content/bone width 0.28 grams per cm^2 (normal, 0.4 ± 0.103 [SD]).

A percutaneous trephine bone biopsy was done and an 8-mm specimen obtained from the iliac crest after tetracycline labeling; it was processed by nondecalcifying methods,[7] sectioned and stained for histomorphometric analysis (Robert Recker, MD, Creighton University, Omaha, Neb) (Table 1). The trabecular bone volume was greatly depressed (6%) and both static and dynamic measures of bone remodeling were

decreased with an osteoid seam width of less than 6 microns, a fractional resorption surface of less than 3% and fractional double-labeled surface of less than 1%. The osteoid volume was uncalculable (none of the grid reticule points fell on osteoid). However, there was a notable amount of trabecular surface covered with very thin osteoid seams such that the fractional osteoid surface measurement was at the mean for normal. The mineralization lag time was depressed at 0.618 years and the bone formation rate was severely depressed.

A pelvic radiograph done eight months after that shown in Figure 1 and before any therapy was begun showed no further evidence of healing. Therapy with a combination of sodium fluoride, vitamin D and calcium was begun but, despite therapeutic serum concentrations of fluoride, there had been no further improvement in the radiographic appearance of the pelvic fractures after ten months of therapy.

Case 2

The patient, a 75-year-old woman, was referred to the Bone and Mineral Clinic at The Oregon Health Sciences University for evaluation of bone disease. She had been well until 12 years earlier when she began to experience back discomfort. Five years before the current evaluation, the diagnosis of Paget's disease or osteomalacia, or both, had been made on the basis of bilateral femoral diaphyseal pseudofractures and an elevated serum alkaline phosphatase level. A regimen of porcine calcitonin, 100 IU given subcutaneously three times per week, was begun for presumed Paget's disease, and 50,000 units of ergocalciferol with 1,500 mg of calcium carbonate per day was administered for presumed osteomalacia. She subsequently sustained several vertebral crush fractures, a right femoral shaft fracture through the pseudofracture and, finally, six months before evaluation, a left femoral shaft fracture at a site distinct from the pseudofracture. All fractures were associated with minimal trauma.

She had undergone a natural menopause 20 years previously and was started on a regimen of diethylstilbestrol at age 72. Vaginal bleeding prompted a hysterectomy eight months later but she continued the diethylstilbestrol therapy. A benign thyroid nodule had been removed at age 68 and the patient received 3 grains of desiccated thyroid daily thereafter. A mastectomy had been done 15 years earlier for a malignant lesion but there was no evidence of recurrent disease. There was no history of other systemic disease, operations or of other medications known to affect bone metabolism.

On physical examination her weight appeared normal, she had only slight kyphosis and was without bone tenderness. Laboratory studies elicited the following values: serum creatinine, 0.7, calcium, 10.7 (normal, 8.5 to 10.5), and phosphorus, 4 mg per dl; total protein, 7.4 grams per dl, and alkaline phosphatase, 181 mU per ml (normal, 35 to 105). Serum AST and bilirubin concentrations were normal. The serum free thyroxine concentration was 1.1 ng per dl (normal, 0.7 to 1.8). A 24-hour urine calcium excretion was 148 mg while on a routine diet. The serum 25-hydroxycholecalciferol level was 152 ng per ml.

A radiographic evaluation showed generalized osteopenia, multiple wedge and compression fractures of the thoracic and lumbar spine and a pseudofracture of the medial aspect of the proximal left femoral shaft (Figure 2, left and middle). Orthopedic plates were present at the site of repair of the previous right femoral fracture, but a linear lucent zone at the site of the fracture had not yet healed (Figure 2, right). Reviews of previous femoral radiographs showed that a pseudofracture very similar to the one apparent in the left femoral shaft had been present at the site of the right femoral fracture.

Radial-photon absorptiometry done at the junction of the distal and middle thirds of the radius showed a bone mineral content of 0.48 grams, a bone width of 1.08 cm and a bone mineral content/bone width of 0.44 grams per cm^2 (normal, $0.57 \pm .085$ [SD]). At the distal radial site (2 cm proximal to the tip of the ulnar styloid) the bone mineral content was 0.51 grams, bone width was 2.28 cm and bone mineral content/bone width was 0.22 grams per cm^2 (normal, 0.4 ± 0.103 [SD]).

Histologic review of bone material obtained at the time the right femoral fracture was reduced five years earlier showed no evidence of Paget's disease, and a further review of radiographic examinations showed no lesions characteristic of Paget's disease. Histologic sections of bone from the reduction of the left femoral fracture were not available. A percutaneous trephine bone biopsy was done and an 8-mm specimen obtained from the left iliac crest was processed by nondecalcifying methods,[7] sectioned and stained for histomorphometric

Figure 1.—Pelvic radiograph of patient 1 showing pseudofractures (arrows) of pelvic rami.

analysis (Robert Recker, MD). That analysis (Table 1) showed greatly depressed trabecular bone volume (5%). Static measures of bone remodeling showed a fractional osteoid surface of 14% and a fractional resorption surface of 6%. Because the trabecular bone volume was very low and there was very little osteoid present, no grid points fell on osteoid and thus the osteoid volume was not derived. There was very little trabecular bone surface on which formation rates could take place and there were no double labels present on trabecular surfaces (fractional double-label surface, mineralization lag time and bone formation rate were therefore not calculated). Nevertheless, trabecular remodeling was apparently depressed. Several areas of double tetracycline labeling appeared on cortical endosteal surfaces, indicating that the patient had taken and absorbed the tetracycline.

The ergocalciferol therapy was discontinued and the serum calcium level subsequently became normal. Other drug therapy was continued and sodium fluoride was added to the regimen. After eight months the patient had sustained several more thoracic vertebral crush fractures but was tolerating the sodium fluoride well. A repeat radiographic examination of the femurs showed no futher evidence of fracture healing.

Discussion

In 1930 Milkman[4] described a case of a patient with nephritis and a generalized skeletal disorder characterized radiographically by osteopenia and multiple, symmetric, ribbonlike zones of decalcification or "pseudofractures." He later termed the condition "multiple spontaneous idiopathic symmetrical fractures" and suggested it represented a new skeletal disease of unknown cause.[8] The actual clinical implications of the presence of pseudofractures evoked considerable controversy[9,10] until 1946 when Albright and co-workers[11] argued convincingly that pseudofractures in fact represent a manifestation of osteomalacia of any cause. They cited work by Looser who had extensively studied the phenomenon of pseudofractures and concluded that mechanical irritation and local microfracture resulted in callous formation within bone.[12,13] The mineralization defect of osteomalacia prevents this "zone of transformation" (umbauzonen) from mineralizing and a radiolucent area (pseudofracture) results. In fact, the histologic appearance of pseudofracture in osteomalacia is indeed that of unmineralized callus.[12] Whereas radiolucent defects similar to pseudofractures may occur in cases of Paget's disease or osteogenesis imperfecta, the other radiographic manifestations of those disorders are always present as well.[11] Stress fractures, another cause of radiolucent zones similar in appearance to pseudofractures, are a result of mechanical stress and heal rapidly following relief of that stress. Albright and associates concluded, therefore, that "ribbon-like zones of decalcification, which occur in otherwise normal-appearing bone, which last months or years without regressing, and which exhibit a marked tendency to be symmetrical, occur only in osteomalacia or rickets."[11] The perception that pseudofractures are a pathognomonic feature of osteomalacia persists in recent reviews.[5,6]

In contrast, the patients in the two cases reported here manifested radiographic lesions indistinguishable from pseudofractures in their appearance and symmetry. Although the inciting events resulting in the appearance of the fractures are unknown (acute or prolonged mechanical stress, perhaps related to the chiropractic manipulation in case 1), their duration is inconsistent with simple traumatic fracture or stress fracture. Whereas the lesions were not in themselves histologically evaluated, histomorphometric analysis of iliac crest bone biopsy specimens in each case showed osteoporosis with greatly depressed indices of bone remodeling. In both cases the presence of pseudofractures resulted in the initial diagnosis of osteomalacia. In case 2 the therapy for presumed

*N = normal

osteomalacia of ergocalciferol and calcium was associated with supranormal concentrations of 25-hydroxycholecalciferol and hypercalcemia, which resolved with discontinuance of the ergocalciferol. The pathophysiology of the osteopenia in these two patients is unknown but several potential risk factors were present in each patient—case 1: age, postmenopausal state and aluminum-containing antacid use; case 2: age, postmenopausal state, desiccated thyroid therapy, ergocalciferol therapy. In case 2 calcitonin therapy probably did not contribute to a progression of osteopenia.

Several other patients have had pseudofractures occurring in the absence of osteomalacia. Richardson and colleagues[14] reported the cases of two premenopausal women who presented with skeletal pain of five to ten years' duration, multiple pseudofractures (nonsymmetric) and no biochemical or histologic evidence of osteomalacia. Treatment with a regimen of calcium and vitamin D resulted in no improvement. Similarly, Perry and associates[15] described the cases of two women (one premenopausal and one postmenopausal) who presented with bilateral, painful femoral pseudofractures of nine months' and eight years' duration. Once again there was no biochemical or histologic evidence of osteomalacia. In one patient, treatment with calcium and vitamin D for presumed osteomalacia resulted in the prompt development of hypercalcemia. A traumatic completion of a femoral neck pseudofracture subsequently occurred, and nonhealing eventually resulted in the need for a total hip replacement.

In Table 2 the clinical characteristics of the two cases described here are shown with those of the four previously reported cases. All were women (three were premenopausal and three postmenopausal) and three had other roentgenographic evidence of osteopenia (vertebral compression fractures). The location of the pseudofractures was most commonly femoral (five of six) but included a wide variety of sites. In four women, all routine biochemical variables were normal, whereas in two there were slight elevations in the serum alkaline phosphatase concentration. Bone histology was characterized by the absence of osteomalacia in all, and pronounced trabecular osteopenia with severely reduced bone remodeling was found in the two present cases. In two patients the treatment of presumed osteomalacia with vitamin D and calcium resulted in the development of hypercalcemia, which was quickly corrected with the withdrawal of therapy. Finally, the potential seriousness of the syndrome is underscored by the occurrence of completed femoral fractures in two patients.

These cases show that multiple pseudofractures characterized by symmetry and delayed resolution are not always the result of an osteomalacic process, and that the metabolic bone disease underlying the development of pseudofractures may include osteoporosis. Potentially more appropriate therapy for osteoporosis was considerably delayed in these patients by the erroneous diagnosis and therapy for osteomalacia. Furthermore, the occurrence of hypercalcemia in two patients with this syndrome (during treatment with vitamin D and calcium) illustrates the risks of treating for presumed osteomalacia without histologic verification. These cases indicate the diagnostic value of the percutaneous bone biopsy and bone histomorphometry, particularly in the absence of the biochemical concomitants of osteomalacia (hypocalcemia, hypophosphatemia and elevated alkaline phosphatase concentration).

The pathophysiology of pseudofractures in the absence of osteomalacia is unknown but may involve defects in new bone formation and a resultant inadequacy of repair at sites of stress or microfracture (the Looser hypothesis). In the two cases reported here, the pronounced depression in bone remodeling and specifically in the rate of new bone formation may have prevented an appropriate healing response, resulting in the development of pseudofractures.

Chronic Myelocytic Leukemia as a Secondary Malignant Condition in a Patient Receiving Prolonged Chemotherapy for Ovarian Carcinoma

MAURIE MARKMAN, MD
San Diego

THE DEVELOPMENT OF secondary malignant conditions in patients who have received chemotherapy for their primary neoplasm is becoming an increasingly recognized and major problem in clinical oncology.[1,2] In cases of ovarian carcinoma, several investigators have found a significantly increased risk for the development of secondary acute nonlymphocytic leukemia in women who have received alkylating agents as therapy for their disease.[3-6] In this report I document the occurrence of an extremely rarely reported secondary malignant disorder, chronic myelocytic leukemia, in a patient who had been given chemotherapy for several years for advanced ovarian carcinoma.

Report of a Case

The patient, a 44-year-old woman, was diagnosed as having stage III poorly differentiated adenocarcinoma of the ovary in March 1980. Following a total abdominal hysterectomy, bilateral salpingo-oophorectomy, omentectomy and tumor debulking, the patient was treated with intravenous administration of cyclophosphamide and doxorubicin hydrochloride. A second-look laparotomy showed residual tumor and the patient was subsequently given eight courses of cisplatin followed by a daily oral regimen of cyclophosphamide for 11 months. Unfortunately, the tumor recurred and an experimental intraperitoneal chemotherapy program was begun that included the administration of cisplatin, cytarabine and doxorubicin on a monthly basis.[7] This treatment was continued for about a year. Leukocyte counts from March 1980 through January 1984 were within the normal range. In February 1984 the leukocyte count had increased to 24,000 per μl and by May 1984 the value was 74,000 per μl. The platelet count had also increased from the normal range to 750,000 per μl in May. Review of the patient's peripheral blood smear showed immature leukocytes (no blast forms) and 2% basophils. On physical examination in May the presence of a palpable spleen was noted for the first time. Due to the patient's poor clinical condition a bone marrow aspirate was not done but a karyotype analysis of the peripheral blood showed the presence of the Philadelphia chromosome—46,XX,t(9,22)—in all the metaphases examined. No specific therapy was instituted and the patient died a month later. The approximate cumulative doses of chemotherapeutic agents the patient received during her illness included 30 grams of cyclophosphamide, 600 mg of doxorubicin, 14 grams of cytarabine and 3.6 grams of cisplatin.

Comment

To the best of my knowledge, this is the first report of chronic myelocytic leukemia developing in a patient receiving chemotherapy for ovarian carcinoma. Several cases have been reported in patients receiving long-term immunosuppressive therapy for renal transplants,[8] and two additional cases have been described of patients with malignant disease (acute lymphoblastic leukemia and Hodgkin's disease)[9,10] receiving chemotherapy in whom chronic myelocytic leukemia developed as a secondary disease process.

While it is certainly possible that the development of chronic myelocytic leukemia in this patient is completely unrelated to her prior chemotherapy, it is reasonable to hypothesize that the almost continuous therapy she received from the onset of her disease in March 1980 until her leukocyte count began rising in February 1984 was somehow implicated in the pathogenesis of this second malignant process. In particular, this patient was treated long term with alkylating agents, which have been most often linked with the occurrence of secondary acute nonlymphocytic leukemia.[1-6] Alkylating agents include cyclophosphamide, melphalan, chlorambucil, thiotepa and mechlorethamine (nitrogen mustard).

It is possible that additional cases of chronic myelocytic leukemia developing as a consequence of therapy might not be recognized unless specifically looked for in the case of a rising leukocyte count, and the presence of immature granulocytes in the peripheral blood can be easily passed off as a leukemoid reaction to the primary malignant lesion.

Gastrointestinal Histoplasmosis in Suspected Acquired Immunodeficiency Syndrome

COLIN M. HAGGERTY, MD
MELVIN C. BRITTON, MD
JOHN M. DORMAN, MD
FRANCIS A. MARZONI, Jr, MD
Palo Alto, California

"ACQUIRED IMMUNODEFICIENCY SYNDROME" is a term used in describing a group of patients who have a profound state of immunologic compromise so that opportunistic infections and a variety of malignant neoplasms develop. The syndrome has assumed epidemic proportions since its recognition in mid-1981.[1-3] Initially described in homosexual men and intravenous drug abusers, additional groups now include Haitian refugees,[4,5] hemophiliacs receiving factor VIII concentrates,[6-8] transfusion recipients,[9] female sexual partners of men with the syndrome,[10] prison inmates[11] and infants in high-risk households.[12,13]

Disseminated histoplasmosis is a rare opportunistic infection occurring in a setting of compromised cellular immunity.[14] Though cases have been recognized in patients with acquired immunodeficiency syndrome,[15,16] very few have been reported to the Centers for Disease Control (CDC). In this report, we describe a case of *Histoplasma*-induced granulomatous colitis seen in a male homosexual as a cecal mass that appeared to be carcinoma. The patient's disseminated fungal infection was associated with autoimmune thrombocytopenia and hypoproliferative anemia. Treatment consisted of surgical resection followed by administration of amphotericin B. To date, no similar case has been described in the literature, nor have any cases of granulomatous colitis caused by *Histoplasma capsulatum* been reported to the AIDS Task Force of the Centers for Disease Control. The fact that the patient presented in a nonendemic area emphasizes the necessity to obtain a thorough history of antecedent travel and exposure.

Report of a Case

A 38-year-old homosexual man was admitted to Stanford University Medical Center for surgical resection of a right lower quadrant mass.

The patient, a resident of northern California for several years, was born and raised in the state of Kentucky. He had returned yearly to the midwest since moving to the West Coast in the early 1970s. The patient had led a homosexual life-style since puberty, having had sexual relations with approximately 200 different partners. His medical history included many episodes of gonorrhea, with two episodes of gonorrhea-induced proctitis. The patient had had recurrent vesicular lesions involving the labial and perianal areas.

Three weeks before admission, the patient consulted his local physician after having for six days dull, continuous right lower quadrant pain unrelated to meals. He had experienced no nausea, vomiting, diaphoresis or malaise, but had noted some looseness of his stools as well as intermittent fevers to 38.5°C (101.3°F). On abdominal examination, the patient had moderate right lower quadrant tenderness without rebound, masses or palpable organs. The right costovertebral angle was minimally tender. A complete blood count showed a hemoglobin of 14.3 grams per dl, a hematocrit of 42.4%, and a leukocyte count of 7,100 per μl with 56% segmented neutrophils, 3% band neutrophils, 20% lymphocytes, 8% monocytes, 10% eosinophils and 3% basophils. Platelets were 85,000 per μl: Results of a serum chemistry profile (SMA-20) were unremarkable. A urine specimen had 4 to 6 erythrocytes per high-power field, with few leukocytes. Culture of a urine specimen was negative for routine pathogens as well as for *Neisseria gonorrheae*. Examination of a stool specimen showed few neutrophils, a moderate number of yeast forms and no ova or parasites.

No specific therapy was begun. The patient's symptoms persisted and blood and urine values remained unchanged. To exclude the possibility of renal colic, an intravenous pyelogram was done; results were within normal limits. A Westergren erythrocyte sedimentation rate was 61 mm per hour (normal $\leq$ 15 mm per hour). A fluorescent antinuclear antibody test was negative and serum complement values were within normal limits.

The patient was referred to the Palo Alto Medical Research Foundation for evaluation. On initial physical examination the patient had moderate right lower quadrant abdominal tenderness with a firm palpable mass. A barium enema showed an intraluminal cecal lesion highly suggestive

Figure 1.—Barium enema showing cecal mass.

of carcinoma (Figure 1). As part of the patient's evaluation, lymphocyte subtyping was done and was notable for an Leu3:Leu2 ratio of 0.12. The total T-cell number (Leu4) was 829 (normal 1,200 to 1,800), with a notably reduced T-helper subpopulation (Leu3 = 90; normal 600 to 1,200) and moderately increased T-suppressor/cytotoxic subpopulation (Leu2 = 739; normal 350 to 600). Results of skin testing revealed anergy to purified protein derivative, mumps, coccidioidin and dermatophyton. A blood specimen was negative for hepatitis B surface antigen. Epstein-Barr antibody titers were consistent with prior infection (viral capsid antigens 1:320; Epstein-Barr nuclear antigen 1:80; early antigen, diffuse and restricted, $< 1:5$). Cytomegalovirus and toxoplasma antibody titers were 1:128 and 1:16, respectively. Quantitative platelet-associated antibody was significantly elevated at 13.5 femtogram IgG per platelet (normal ≤ 5.3).

The patient was admitted to Stanford University Medical Center for resection of the cecal mass. Laboratory evaluation on admission showed the following: a hemoglobin of 11.1 grams per dl, a hematocrit of 33.4% and a leukocyte count of 4,700 per μl (47% segmented neutrophils, 11% band neutrophils, 29% lymphocytes, 6% monocytes and 7% eosinophils). The platelet count was 90,000 per μl. A urine specimen contained no erythrocytes and a chest roentgenogram was normal. At operation the patient had a large inflammatory mass involving the right colon and the greater omentum. There was extensive mesenteric lymphadenopathy and numerous serosal implants.

Pathologic examination of the resected right colon showed a circumferential lesion near the ileocecal valve measuring 4 by 7 cm and having a "heaped-up," ulcerated appearance (Figure 2). On sectioning, the mass was found to be composed of firm, white, coarse tissue extending through the colonic wall and into the pericolonic fat. The adjacent mesocolon was thickened and contained a chain of enlarged lymph nodes. Microscopic examination showed intense noncaseating granulomatous inflammation. Stains for acid-fast organisms were negative, but stains for fungi showed striking infestation with budding yeast forms, occurring intracellularly and extracellularly. Cultures of all specimens grew *H capsulatum*. A left iliac bone marrow biopsy specimen obtained at laparotomy showed normal cellularity without granulomas and was negative for pathogens when cultured.

The patient's postoperative course was uncomplicated. His hematocrit continued to decrease, and he ultimately required transfusion. Stool specimens were intermittently positive for occult blood. A reticulocyte count was 0.3%. Mean corpuscular volume was 84 cu microns. The serum iron value was 64 μg per dl (normal value is 40 to 140 μg per dl) and total iron-binding capacity was 144 μg per dl (normal 250 to 400 μg per dl), yielding a saturation of 44%. Direct and indirect Coombs' testing was negative. The platelet count stabilized at 90,000 per μl. On the sixth postoperative day, therapy with amphotericin B was begun and the patient ultimately received a total dose of 2.5 grams over the ensuing three months.

Shortly after discharge, a cough developed and the patient had a pulmonary infiltrate suggestive of early *Pneumocystis* pneumonia. Fiberoptic bronchoscopy with transbronchial biopsy and bronchoalveolar lavage were negative for parasitic, fungal, bacterial or neoplastic disease. The patient's pneumonitis resolved without specific therapy. At the time this manuscript was prepared (four months after completion of amphotericin therapy), the patient had no signs or symptoms of disseminated histoplasmosis or other opportunistic infection. Repeat lymphocyte subtyping has yielded abnormal results nearly identical to those previously obtained.

Discussion

This case helps to establish *Histoplasma capsulatum* as a pathogen that must be considered in patients with the acquired immunodeficiency syndrome (AIDS). As the current case definition of the CDC does not include disseminated histoplasmosis, our patient does not strictly satisfy the criteria for AIDS. Nevertheless, because dissemination is rare in otherwise normal persons, this case argues for the addition of disseminated histoplasmosis to the list of fungal infections in the CDC's criteria. The fact that this infection manifested itself in a nonendemic area demonstrates the necessity of obtaining an accurate travel history and the importance of considering endogenous reinfection in immunologically suppressed patients.[17] This is especially pertinent because

Figure 2.—Gross pathologic appearance of resected right colon with cecal mass.

most cases of AIDS are reported from areas where histoplasmosis is not a prevalent infectious disease problem.[18]

Gastrointestinal tract involvement occurs in up to 75% of cases of disseminated histoplasmosis.[14,19] Nevertheless, clinically obvious gastrointestinal involvement is infrequent and oral lesions are far more common than colonic manifestations. In cases where the colon is involved, the lesion usually begins as an elevated plaque, with progression to a localized granulomatous ulcer. Uncommonly, such foci will assume a different pattern of growth, resulting in a mass that can simulate carcinoma as a constricting ("apple core") lesion[19] or, as in our patient, as a fungating intraluminal tumor.

The presence of autoimmune thrombocytopenia in this patient is an interesting finding. Morris and associates have described patients with AIDS who were also noted to have thrombocytopenia and elevated platelet IgG values.[20] *Histoplasma*-induced autoimmune thrombocytopenia has likewise been reported.[21] Whether AIDS or *Histoplasma*-induced thrombocytopenia is important in this case cannot be determined.

Although cases of hemolytic and hypoproliferative anemia have been reported in patients with Kaposi's sarcoma,[22,23] anemia is not recognized as a common manifestation of AIDS per se. Our patient had an inadequate marrow response to continued postoperative gastrointestinal blood loss. His serum iron and iron-binding capacity are consistent with what has been recognized as "anemia of chronic inflammation."

Untreated, the mortality of disseminated histoplasmosis in patients who do not have this syndrome has been as high as 83%.[24] The efficacy of therapy with amphotericin B is well established, although total dosages must exceed 2 grams.[25] Ketoconazole has been effective in selected cases of disseminated histoplasmosis and its use is associated with far less toxicity than for amphotericin B.[26] This new imidazole derivative would have been particularly advantageous for our patient, given his increased likelihood for new fungal infections that would require additional amphotericin B. Unfortunately, ketoconazole's efficacy for treatment of disseminated histoplasmosis in immunosuppressed patients has been disappointing.[27,28]

Factitious Hematuria and Self-Induced *Candida albicans* Fungemia

GEOFFREY H. GORDON, MD
Portland

ROYCE CHRYS, MD
San Francisco

PATIENTS WITH FACTITIOUS disorders are characterized by their conscious production of spurious historical, physical or laboratory data for no apparent reason other than to assume the patient role.[1] These patients represent a diverse psychiatric group and may simulate a wide variety of medical problems. In this report we describe a case of a patient with factitious hematuria, fever and *Candida albicans* fungemia and review the diagnosis and management of factitious disorders.

(Gordon GH, Chrys R: Factitious hematuria and self-induced *Candida albicans* fungemia. West J Med 1985 Aug; 143:246-249)

From the Departments of Medicine and Psychiatry, Veterans Administration Medical Center, Long Beach, and the University of California, Irvine, California College of Medicine. Dr Gordon is now affiliated with the Division of General Medicine, Department of Medicine, The Oregon Health Sciences University, and the Ambulatory Care and Medical Services, Veterans Administration Medical Center, Portland. Dr Chrys is now a transitional intern at St Mary's Hospital and Medical Center, San Francisco.

Report of a Case

The patient, a 23-year-old man, presented to an emergency room with a two-day history of right lower quadrant pain and gross hematuria accompanied by nausea, vomiting and mild dysuria. He stated that his right kidney had been "ruptured" during a parachute jump while he was serving military duty in 1978, producing transient hematuria. He also gave a history of operations in 1979 and 1982 to "straighten a kinked ureter" on the right and an appendectomy in 1980. There was no history of nephrolithiasis, dysuria, fever or recent trauma.

On physical examination he was in mild distress, with an oral temperature of 36.6°C (97.3°F), pulse 74 beats per minute, blood pressure 100/70 mm of mercury and respiratory rate 16. Positive physical findings were limited to the abdomen. Two midline surgical scars extended from the umbilicus to the pubis and an appendectomy scar was present. Bowel sounds were normal. There was tenderness to light palpation in the right lower quadrant without guarding or rebound tenderness and he had a 3-cm right inguinal hernia that was easily reducible. Results of rectal and genital examinations were normal and there was no tenderness at the costovertebral angle. Laboratory data included an analysis of urine showing erythrocytes too numerous to count, 0 to 2 leukocytes per high power field, 1+ protein and no bacteria. Serum glucose level, electrolytes, complete blood count, prothrombin time, partial thromboplastin time, platelet count and blood urea nitrogen and serum creatinine levels were all normal. X-ray films of the chest and abdomen also were normal.

The patient was admitted to the Urology Service where an intravenous pyelogram showed an ectopic and malrotated right pelvic kidney with mild pyelocaliectasis. The right ureter was short but of normal caliber, and the left kidney was normal. Cystoscopy and retrograde pyelography failed to show a source of bleeding. On renal angiography there were double renal arteries on both sides but no other abnormalities. A urine specimen obtained by catheterization contained no blood. The patient's abdominal pain continued and he requested frequent parenteral administration of narcotics. Several institutions where he claimed to have received treatment had no record of his care. Factitious hematuria was suspected, and the nursing staff was instructed to observe the patient urinate.

On the seventh through the tenth hospital days, oral temperature elevations were recorded ranging from 39°C (101.7°F) to 40.7°C (104.7°F). Temperature elevations were unaccompanied by tachycardia or leukocytosis. Cultures of blood and urine specimens were carried out and empiric antibiotic therapy for a presumptive urinary tract infection was begun. By the 18th hospital day the patient's hematuria and fever had resolved, but culture of four of eight blood specimens obtained on three separate days during his febrile episodes grew *Candida albicans*. The patient was transferred to the Medical Service where a careful physical examination showed no evidence of fungal endocarditis or disseminated fungal infection. One day following transfer, the patient complained of a stiff neck and was found to have an oral temperature of 38.6°C (101.0°F). A lumbar puncture was done that yielded clear fluid with a glucose level of 72 mg per dl, a protein value of 41 mg per dl and no cells. Cultures of two more blood specimens taken on the day of transfer agai grew *C albicans*. Cultures of several urine and throat speci mens showed no growth of *Candida*, and an echocardiogram, gallium scan and computed tomographic study of the abdomen failed to show a focus of infection.

On the 22nd hospital day, acting on information received from a roommate, the patient's personal belongings were searched and several tuberculin syringes and a vial of milky-white substance were recovered. Laboratory analysis showed that the substance was magnesium-containing antacid that grew *C albicans* on culture. When the patient was confronted with these findings, he confessed to injecting the substance intravenously through the antecubital fossa. He said he did not know that the antacid was contaminated and that he injected himself to relieve pain and to draw attention to his inguinal hernia, which he wanted repaired. After the vial and syringes were removed from the bedside, the patient's fevers disappeared and eight subsequent blood cultures were negative for *C albicans*.

Psychiatric consultation was obtained, and the patient was transferred voluntarily to the Psychiatry Service. He stated that his parents had divorced when he was 6 months old and that he had been raised by his father, in whom a chronic illness developed following radiation exposure during military duty. The patient believed that his pelvic kidney and inguinal hernia were genetic defects related to his father's radiation exposure. He admitted that he had abused drugs intravenously in the past and recently had been released from prison in Texas after serving a one-year term for passing bad checks. He reported having difficulty reintegrating into society and requested that his hospital discharge be delayed until he could make plans for living outside the hospital. It was discovered that the patient had been admitted to hospital with hematuria in the San Diego Veterans Administration Medical Center one month before admission but had used a false social security number and military service dates. Results of psychological testing indicated poor insight and impulse control and a tendency to somatize anxiety. He became increasingly hostile and noncompliant on the Psychiatry Service and was discharged on the 58th hospital day with a psychiatric diagnosis of borderline personality disorder with histrionic and schizoid features, and adjustment disorder with anxious and depressed mood.

Comment

Factitious Disorders

The incidence of factitious disorders, particularly among outpatients, is unknown; however, 41 inpatient cases were reported from a teaching hospital during a ten-year period.[2] Patients with factitious disorders may present with symptoms and signs referable to any organ system. The complaints may be either dramatic and urgent or complex and subtle. As in the case reported here, the presence of a preexisting pathologic condition or a self-induced pathophysiologic state can make a spurious history seem more credible. Patients may also present with several simultaneous factitious disorders.[2-5]

Gross hematuria with or without renal colic is a common factitious disorder and may be produced by adding blood to urine after voiding or by traumatizing the urethra.[3,4,6-10] Some patients can actually simulate the roentgenographic appearance or passage of renal calculi.[9,10] Although ectopic or

malrotated kidneys may be associated with abdominal or flank pain, pyuria, proteinuria and recurrent urinary tract infections.[11] it seems likely that our patient's hematuria was factitious because results of analysis of urine were otherwise unremarkable and because urine obtained by catheterization never contained blood.

Factitious fever is also a well-documented syndrome, with a prevalence of 2% to 9% in patients with fever of unknown origin in several large series.[3-5,12,13] Factitious fever may be produced by various methods of thermometer manipulation or by self-injection of contaminated or pyrogenic substances. Thermometer manipulation results in the apparent loss of normal diurnal temperature variation and is unaccompanied by skin warmth, tachycardia, diaphoresis and leukocytosis when thermometer readings are elevated. Elevated thermometer readings produced by thermometer manipulation may differ greatly from temperature readings obtained with a nurse or physician in constant attendance, or from different body orifices, leading to the appearance of widely and rapidly fluctuating thermometer readings.[3,5] Our patient's temperature readings were taken in the presence of hospital staff but were unaccompanied by tachycardia or leukocytosis. His fevers may have been a physiologic response to the injection of foreign, contaminated material; on the other hand, fever in the setting of another factitious illness is often itself factitious, and patients with self-induced infections have been known to manipulate their thermometers.[4,5]

In two recent reports, self-induced infections accounted for 41% of cases of factitious fever[5] and 30% of all cases of factitious disorders.[2] The most frequent clinical presentations of self-induced infections are chronic recurrent subcutaneous abscesses and bacteremias. A pattern of several infections over many years is usual before the factitious cause is recognized. Self-injection from syringes filled with contaminated substances is a common method of inoculation, and Gram-negative enteric organisms and Gram-positive cocci are the usual pathogens. Most self-induced infections are simultaneously or consecutively polymicrobial unless pure bacterial cultures are injected.[5,13] Other materials that have been injected include air, dirt, saliva, human and animal feces, foot washings, tetanus toxoid, milk, deodorant, alcohol and lighter fluid.[4,5,13] Our computerized search of the medical literature failed to find published reports of the self-administration or effects of oral antacid preparations given parenterally. Furthermore, we found only two cases of *C albicans* fungemia associated with self-induced infection.[5,13] Both were associated with cases of polymicrobial bacteremia, and one was felt to be due to a contaminated intravenous catheter.[5] Although *Candida* endocarditis has been described in intravenous drug abusers, *C albicans* fungemia associated with infected urinary or intravenous catheters may resolve spontaneously in immunocompetent hosts following catheter removal.[14] After we removed the contaminated vial and syringes from the bedside, blood cultures for *C albicans* were persistently negative and the patient had a benign clinical course, indicating that neither endocarditis nor disseminated tissue invasion was present.

Psychopathology

Psychiatrically, patients with factitious disorders are a heterogeneous group with diagnoses including neurosis, personality disorders, organic mental states and psychosis.[15] Some have borderline personality disorder, which is characterized by intense anger and depression, impulsive self-destructive behavior, unstable relationships with others (including physicians) and brief episodes of psychosis.[5,16] Patients with factitious disorders may have a history of early rejection or abandonment by their parents or early exposure to chronic illness, physicians or institutional care. They also may have education or experience in medically related areas and real or imagined physical abnormalities. For some of these patients, admission to hospital and care by physicians and nurses may represent an unconscious reenactment of disturbances in early relationships with parents over issues of trust, dependency, mastery, aggression and guilt.[17,18]

Some patients produce only one or occasional factitious disorders in response to stress and have no other evidence of psychiatric impairment. Others with a variant of factitious disorder termed Munchausen's syndrome have a history of drug abuse and sociopathic, criminal or psychotic behavior that is obscured by their gross impostures and pathological lying.[15-18] Although pain control is often an issue, they readily accept painful invasive procedures. These patients travel widely, simulate abdominal, hemorrhagic or other emergencies and may leave a hospital abruptly following a hostile confrontation with their physicians. Our patient's history of drug abuse and imposture and his hostile, noncompliant response to psychiatric hospital admission suggest that he belongs in this Munchausen's syndrome subgroup. Patients with another variant of factitious disorder have been described as immature, passive and hypochondriacal.[2,4] These patients are more likely to be young women and to have worked or trained in a medically related field. They are also more likely to respond favorably to confrontation and ongoing medical or psychiatric care. Patients in any of these groups may present with severe or life-threatening factitious disorders.

Diagnosis

Patients with factitious disorders usually present unduly long, complex or improbable histories filled with medical or pseudomedical terminology. Early recognition of these disorders, therefore, requires that historical or other inconsistencies be clarified as they arise. Other hospitals and physicians, insurance companies, employers or relatives may also provide useful diagnostic information. Once a factitious disorder is suspected, the patient should be observed carefully for behavior confirming this diagnosis. Occasionally, as in the case reported here, materials used to produce the factitious disorder may be discovered. When enough evidence to suggest the diagnosis has been gathered, the patient should be confronted in a supportive and nonthreatening manner, without implying abandonment by the primary physician.[2,5,13,16] Plans for continued medical and psychiatric treatment should be presented to the patient at the time of confrontation. Although confrontation rarely results in confession, even when the evidence is convincing, it may relieve an impasse between the patient and the medical staff or result in disappearance of the factitious disease. A few patients make their deception so obvious that they seem to invite confrontation and leave the hospital angrily after a short stay. In others, confrontation may lead to further self-destructive be-

havior or flight from treatment.[8] A psychiatric consultant may help to identify patients at high risk for reacting poorly to confrontation and may also assist with the confrontation process.

Treatment

The patient in the case reported here may have accepted psychiatric treatment as a condition of continued hospital stay. Most patients with factitious disorders are resistant to psychiatric intervention, however, and no psychiatric treatment approaches have proved consistently effective.[15,16] Many of these patients are also unable to maintain a therapeutic relationship with a primary care physician, and their long-term medical care is often fragmented and episodic. Patients who are willing to be followed in a primary care setting should be given careful medical evaluations, and those who are overly concerned about a real or imagined physical abnormality should be reassured. A schedule of regular outpatient visits should then be established.[19] This schedule relieves the patient's fears of abandonment by the physician and removes the contingency of further visits on the presence of disease. During the actual visits, a supportive, noninterpretive approach should be taken and healthy psychosocial behaviors such as appropriate recognition and expression of feelings should be reinforced by the physician's interest and approval. Formal contracts may be used to limit the use of medications, procedures and visits to other physicians and the production of factitious disease. For patients with borderline personality disorder, unrealistic expectations for care and dramatic responses to disappointment should be anticipated.[5,16] Because borderline patients frequently characterize others as "all good" or "all bad," physicians and staff must agree on a consistent treatment approach. It must be emphasized that patients with factitious disorders are poorly understood and that many are incorrigible or present major treatment problems. Physicians who expect patients to become cured, insightful or grateful will need to lower these expectations to avoid anger and disappointment.

A key aspect of treatment is avoiding negative attitudes toward the patient. Although these patients intentionally mislead or manipulate physicians, many regard physicians as allies and do not derive pleasure from deceiving them. Physicians should thus regard the production of factitious disease as an emotional disorder rather than malicious trickery.[2,10] Anger at the patient may result in an exaggerated attitude of mistrust, neglect of coexistent medical problems or outright abandonment. Similarly, guilt related to missing the diagnosis, accusing the patient of lying or feeling helpless may result in an intense or exclusive focus on medical or surgical problems and neglect of pertinent psychosocial issues.[16] Discussing the case with a psychiatrist may help the primary physician exclude other psychiatric disorders and plan an effective management strategy. Although the prognosis for the disappearance of a factitious disorder is guarded for patients with psychosis or borderline personality disorder, patients with good premorbid psychosocial function may recover and have no further factitious episodes.[2]

The diagnosis and management of factitious disorders pose some unique legal and ethical questions.[20] Failing to initiate appropriate emergency care until a true pathophysiologic state is ruled out, circulating photographs of a patient to other physicians or suddenly abandoning a patient may be grounds for a lawsuit. Searching a patient's belongings for evidence of factitious disease without his or her knowledge or consent has been justified on the basis of suicidal risk[2]; however, few of these patients have been successfully committed to psychiatric institutions as a danger to themselves.[15] Finally, the physician's duty to protect a patient's integrity and confidentiality is challenged by the deceit and may conflict with the physician's duty to inform affected family members, other physicians and third-party payers of the factitious nature of the disorder.

Correspondence

The Editorial Board will be pleased to receive and consider for publication correspondence containing information of interest to physicians or commenting on issues of the day. Letters ordinarily should not exceed 600 words, and must be typewritten, double-spaced and submitted in duplicate (the original typescript and one copy). Authors will be given an opportunity to review any substantial editing or abridgement before publication.

Anticholinergic Agents in Cicutoxin Poisoning

TO THE EDITOR: The recent article by Landers and co-workers[1] is an excellent toxicologic review of what is reputed to be the most poisonous plant in North America,[2] the water hemlock. As noted by the authors, previous publications have indicated that cicutoxin-induced seizure activity appears to result from an overstimulation of central cholinergic pathways.[3,4] Starreveld and Hope[4] suggested that perhaps an anticholinergic agent, such as atropine, might be of value in mitigating the convulsive effects of this plant. We have published the results of a study[5] which examined the possible use of anticholinergic agents in the treatment of *Cicuta douglasii* poisoning.

Our study utilized 35-day-old, C-1 mice which were placed, one each, in plastic boxes to avoid any effects of grouping. A dilute alcoholic extract was prepared from the root of verified *Cicuta douglasii.* Dose-effect data on seizure activity were collected using five doses (intraperitoneally) of ten mice per dose. Similar data were collected on mice that had been pretreated with benztropine and biperiden. We found no significant difference in the convulsive dose-50% (CD_{50}) between the control animals and those treated with the anticholinergic agents. In addition to this information, we collected data comparing the CD_{50} of control animals versus animals pretreated with physostigmine. This phase of the study was to examine the hypothesis that cholinergic stimulation would have an additive seizure-inducing effect with concomitantly administered cicutoxin by lowering the seizure threshold. As with the first phase of the study, no significant difference was noted between pretreated mice and controls. The final phase of the study compared control animals with those pretreated with diazepam. In contrast to the initial phases of the study, we found diazepam to significantly elevate the CD_{50} in mice ($P < .05$).

Our results suggest that the convulsive effects of water hemlock are neither reduced by the anticholinergic agents benztropine or biperiden nor increased by the use of the cholinergic agonist physostigmine. Use of diazepam, on the other hand, significantly reduces seizure activity, when compared with findings in controls. As suggested by Landers, and confirmed by our study, cicutoxin-induced seizures should be controlled with intravenous administration of diazepam. We hope that precious time and effort will not be wasted in the clinical setting attempting to utilize central anticholinergic agents in treating water hemlock poisoning.

A Medicaid Success Story

TO THE EDITOR: Dr Boni's letter "Abolish Medi-Cal"[1] struck a responsive cord in me. We all have our private horror stories to tell about this "system for denying payment for . . . medical care." I would like to share with Dr Boni and other readers a success story involving that same system. This can perhaps give an answer to the question of how physicians in a "less affluent area" can provide care to poor patients through the current Medicaid system (Medi-Cal in California).

It is clear that the current system is a "two tier system"—in fact, if not in theory. The solution we have arrived at accepts this fact and relies upon a combination of Medi-Cal reimbursement and volunteered physician services to provide care to 2,000 or more patients on state aid.

Realizing that "If I continue to treat poor patients it will be at my own expense," many physicians had, in the past, simply refused to treat such patients or severely limited their practices. Medicaid patients had limited access to care and physicians who treated such patients had to pass on their losses to their private sector patients.

In 1983 a group of doctors in my locality organized a nonprofit clinic devoted exclusively to the care of Medi-Cal patients. No other form of reimbursement is accepted. Ordinary outpatient services are provided by nurse practitioners and physician's assistants under close supervision by volunteer physicians in a group practice next door. Patients requiring physician services are seen by a panel of volunteer physicians who staff "clinics" on their own time, free of charge. In serious emergencies, patients are sent to the hospital's emergency room next door. Another group of physi-

cians provide care through their offices for obstetrical or inpatient hospital care on a rotating basis, charging Medi-Cal for their services. The clinic staff does the necessary paperwork and phone calls to obtain treatment authorization from Medi-Cal when hospital admission or surgery is required.

This approach has proved quite successful. Patients are assured the availability of care, and physicians are able to fulfill their desire to do their share of charity care without burdening their offices with Medi-Cal paperwork. The clinic itself has been able to generate enough charges, even at low Medi-Cal reimbursement rates, to pay the overhead and personnel costs.

There is no doubt that the current Medi-Cal program is inefficient, expensive and filled with impediments to reimbursement for provision of medical care. These problems can be solved in part by using physicians' traditional willingness to provide some free care as part of their professional obligation.

Dysthyroid Ophthalmopathy

To the Editor: We read with interest the article "The Ophthalmopathy of Graves' Disease" in the April 1985 issue.[1] Our experience with several hundred patients with dysthyroid ophthalmopathy has allowed us to formulate a protocol for their management.

During the acute phase, we recommend several supportive measures, including elevation of the head of the bed and artificial tear drops to the eyes. In addition to corneal exposure from proptosis and eyelid retraction, many of these patients have decreased tear production. We feel that control of any thyroid gland abnormalities is important to the general health of the patient, but have not seen any correlation between this control and the progression of the orbitopathy. In general, the orbitopathy tends to run its course. Medicines, surgery and even radiation may make the patient more comfortable, preserve the vision and more rapidly restore function. Nonetheless, the disease process itself must run its course until quiescence is achieved. Prednisone is occasionally of use in patients with severe inflammatory reactions, but should not be used on a regular basis and should not be used for longer than several weeks.

During the acute phase the patient should be examined regularly by an ophthalmologist for evidence of dysthyroid optic neuropathy. This is most likely caused by the enlarging extraocular muscles compressing the optic nerve at the apex. It is interesting to note that in patients with maximal posterior muscle enlargement there is minimal proptosis but often optic neuropathy develops. When optic neuropathy is detected, we institute a trial of corticosteroid therapy for several weeks. Oral administration of prednisone may minimize orbital apex edema and allow the patient to pass through this phase of the orbitopathy without surgical intervention or irradiation. If optic neuropathy persists in a patient on a regimen of 100 mg of prednisone a day for several weeks, surgical orbital decompression is carried out. Careful attention is given to decompression of the orbital apex. It is only after failure of corticosteroids and surgical decompression to relieve the optic neuropathy that we advise radiation therapy. In management of more than 150 cases we have used radiation therapy in three patients. In our experience, irradiation causes extreme fibrosis of the orbital contents and increased difficulty with the patient's future rehabilitation. We strongly feel that radiation therapy for nonmalignant maladies is to be avoided when possible.

Once the acute phase has passed and the patient is stable for six to nine months, surgical rehabilitation may be considered in a stepwise fashion. We feel that there are four sequential stages to this rehabilitation. Stage one is orbital decompression to move the eyes back to a more posterior and protected position in the orbit. Stage two is an extraocular muscle surgical procedure to correct diplopia. Stage three is eyelid malposition correction (such as recession of eyelid retraction). Stage four is removal of excess eyelid skin and fat that has formed as a result of the disease process. Each stage must be considered in order. Any unnecessary stage may be skipped. Surgical rehabilitation done in this order provides better results and keeps the number of procedures to a minimum. For example, strabismus operations carried out on patients with proptosis recess the muscles and allow the globes to become more proptotic. Subsequent orbital decompression moves the eyes and muscle cones posteriorly and often results in a change in muscle cone position with associated induced strabismus. The patient then requires an additional strabismus operation. Movement of the globes and muscle cones (decompression) results in a change in the position of the extraocular muscles and eyelid retractors. Movement of the extraocular muscles results in a change in position of the eyelid retractors. The logic of the four stage approach to surgical rehabilitation, therefore, is clear. We have been very pleased with the results when this staged approach is used.

Familial Hiatal Hernia

To the Editor: In his letter in the November 1984 issue,[1] Dr Leung reports on a family in which six members were affected with a hiatal hernia. He goes on to observe that this may be the first recorded example of the familial occurrence of the disorder. While this may be true of the United States and Canada, it is certainly not true of the European literature.

In 1970 I published with P. Froggatt a paper[2] drawing attention to the etiologic role of heredity in hiatal hernia. In that article we undertook a comprehensive review of the world literature and reported on a family with eight unequivo-

cally affected members in three successive generations. A simple autosomal dominant inheritance due to a single abnormal gene was postulated. I have since investigated another family showing a similar mode of inheritance. In this second family there are 21 members with a hiatal hernia (all proved radiologically) in four successive generations. Apart from these high risk families, additional studies have shown that younger siblings of children with a hiatal hernia have an approximate 10% risk of being similarly affected.[3] That a hereditary factor contributes to the etiology of many cases of hiatal hernia would therefore seem irrefutable.

Iridocyclitis Is Not Characteristic of Still's Disease

To the Editor: In his otherwise excellent review of adult Still's disease,[1] Dr Larson states, "Interestingly iridocyclitis is apparently not a problem in adults." The misleading implication is that iridocyclitis is common in children with Still's disease. It certainly is not.

The term juvenile rheumatoid arthritis (JRA) is unfortunately applied to a diverse group of diseases. In at least two subsets of patients, JRA is strongly associated with iridocyclitis. In one subset a pauciarticular arthritis develops usually between the ages of 2 and 6. This subset tends to be female, tends to develop antinuclear antibodies (ANA) and frequently develops bilateral, chronic iridocyclitis with sequelae such as band keratopathy and cataract formation.[2,3] A pauciarticular arthritis also develops in a second subset, with a later median age of onset. In this subset, test findings usually are HLA-B27 positive and ANA negative, and frequently sacroiliitis develops.[3,4] The iridocyclitis found in this subset is acute and predominates in one eye. The ocular disease is usually more benign than in the former group. Neither of these subsets have hallmarks of Still's disease, such as evanescent rash, high fever, lymphadenopathy, leukocytosis or hepatosplenomegaly.

In one survey of 668 patients with JRA, 68 patients had iridocyclitis but none of these were included in the subset of JRA characterized by rash and high fever.[4] In another series, 368 children with JRA underwent periodic eye examinations. Of the children, 66 had systemic onset disease with fevers, rash, adenopathy and visceral involvement. In none of these patients did iridocyclitis develop.[5] Finally, in a third series acute iridocyclitis was found in 2 of 36 patients with "systemic onset" JRA.[6]

By combining these three large series, one finds an incidence of iridocyclitis in juvenile Still's disease of less than 2%. In Dr Larson's review of 59 patients with adult Still's disease, an absence of iridocyclitis is not a significant deviation from the incidence in childhood disease. By contrast, iridocyclitis develops in 53% of children with ANA-positive, early-onset, pauciarticular JRA[2] and in 25% of children with pauciarticular, late-onset, HLA-B27-associated JRA when followed into adulthood.[4]

JRA is a misleading disease description. The term Still's disease for both children and adults should be reserved for a very distinct subset of patients in whom iridocyclitis is rarely found to occur despite diligent ophthalmologic surveillance.

HLA Typing in Hashitoxic Periodic Paralysis

To the Editor: I read with great interest the letter "Thyrotoxic periodic paralysis in Navajos—HLA typing" by Williams.[1] Dr Williams has provided us with a lot of insight about HLA typing in patients with thyrotoxic periodic paralysis.

I have reported the cases of two Chinese brothers with hashitoxicosis (Graves' disease with Hashimoto's thyroiditis) evidenced by the presence of thyroid antibodies in addition to elevated thyroxine levels.[2] These two brothers also had a history of periodic paralysis. The association of familial occurrence of hashitoxicosis and periodic paralysis has not been reported before.

Recently, HLA typing was carried out on these two brothers and showed the following antigens: A2, Aw33, Bw58, Bw60, Cw3, Cw4; and Aw24, A11, Bw22, Bw60, Cw3 and Cw7, respectively. Thus these two patients share the Bw60 and Cw3 antigens in common. Further case reports are necessary to delineate the link between these antigens and hashitoxic periodic paralysis.

Topics in Primary Care Medicine

Orthostatic Hypotension

MAJ KURT KROENKE, MC, USA, *San Antonio, Texas*

"Topics in Primary Care Medicine" presents articles on common diagnostic or therapeutic problems encountered in primary care practice. Physicians interested in contributing to the series are encouraged to contact the series' editors.

BERNARD LO, MD
STEPHEN J. McPHEE, MD
Series' Editors

Hypertension, from diagnosis to treatment, is a fairly well-defined medical entity. Hypotension is a hazier issue. There is first a considerable number of people whose low blood pressure represents but one end of a bell-shaped curve. With systolic pressures ranging from 80 to 110 mm of mercury and, without symptoms, they can be reassured of a normal if not lengthened life expectancy. At the other extreme is shock, a medical emergency characterized by pressures insufficient to perfuse vital organs. A less critical but quite common clinical problem is that of orthostatic hypotension, wherein the decline in blood pressure is elicited by the assumption of an upright posture. A practical approach to its etiology, diagnosis and treatment is presented.

Physiology

Due to gravitational forces, standing would invariably produce a decline in blood pressure and cerebral perfusion were it not for a homeostatic chain of events. Pooling of blood in the legs leads to a transient drop in cardiac output and, consequently, blood pressure. Simultaneously, however, baroreceptors in the aorta and carotid bodies sense this drop and send a message centrally. Reflex sympathetic stimulation results in cardioacceleration and both venous and arterial constriction. The augmented venous return and increased heart rate boost the cardiac output, which, combined with higher peripheral vascular resistance, returns the blood pressure towards baseline. In a normal person, this happens quickly without symptoms of major sphygmomanometric perturbations.

In actuality, minor changes can occur. With standing, the systolic pressure tends to fall, the pulse quickens and the diastolic pressure remains unchanged or rises slightly. There are, however, no agreed-upon normal limits. Averages from the literature would suggest that a drop in systolic pressure of as much as 20 mm of mercury, a decline in diastolic pressure of 10 mm of mercury and a rise in pulse rate of 20 beats per minute could be considered normal—a rule of "20-10-20." Some authors suggest that a drop of as much as 30/15 mm of mercury may be normal; however, others feel that *any* drop in diastolic pressure is abnormal. More important is the occurrence of symptoms, typically dizziness, attendant upon decreased cerebral perfusion. It is this dyad of an objective drop in blood pressure coupled with subjective light-headedness that produces the disease, orthostatic hypotension. Dizziness is the most common complaint; however, angina, blurred vision, nausea and syncope may occur. Symptoms are frequently worse in the early morning and following meals, the latter due to splanchnic diversion of blood flow.

Etiology

The major causes of orthostatic hypotension are outlined in Table 1. Patients with volume depletion often present with orthostatic hypotension and, if recognized, are the most treatable group. Hypovolemia due to gastrointestinal losses or sweating or bleeding becomes apparent on a careful history taking and physical examination. More subtle is the volume depletion stemming from mineralocorticoid deficiency. Though uncommon, Addison's disease should be considered in unexplained cases. The other major treatable cause of orthostatic hypotension is that related to drugs. Though most drugs listed in the *Physician's Desk Reference* are reported to cause dizziness, the major offenders are psychotropic and cardiovascular drugs. There are differences within categories. Among antihypertensives in common use, methyldopa, prazosin hydrochloride, clonidine and diuretics require particular caution. Among tricyclic antidepressants, imipramine hydrochloride causes frequent orthostasis, whereas nortriptyline hydrochloride may be better tolerated.

Neurologic disease usually works through a common pathway of autonomic dysfunction. In rare cases, central ner-

vous system or spinal cord pathologic conditions, such as strokes, tumors or trauma, underlie the hypotension. More commonly, the mechanism is a peripheral neuropathy, usually diabetes, but on occasion the neuropathy of alcoholism, amyloidosis or uremia. Sometimes the autonomic system alone goes awry. Primary autonomic failure can occur as a central or preganglionic type (Shy-Drager syndrome) and a peripheral or postganglionic form. The preganglionic form has also been called multiple systems atrophy because of the eventual development of central nervous system signs such as corticospinal, cranial nerve, extrapyramidal and cerebellar abnormalities. Both this and the peripheral variant, idiopathic orthostatic hypotension, have been extensively reviewed in the literature. The rise in plasma norepinephrine levels that occurs in normal persons on standing fails to occur in cases of either multiple systems atrophy or idiopathic orthostatic hypotension. In multiple systems atrophy this is presumed due to a failure in central regulation and in idiopathic orthostatic hypotension to an actual depletion of catecholamine stores or degeneration of nerve terminals.

TABLE 1.—*Major Causes of Orthostatic Hypotension*

- Volume Depletion
  - Extrarenal losses (hemorrhage, gastrointestinal losses, sweating and so forth)
  - Mineralocorticoid deficiency (Addison's disease)
- Drugs
  - Psychotropic (tricyclics, phenothiazines, sedatives, narcotics, levodopa)
  - Cardiovascular (antihypertensives, calcium channel blockers, nitrates)
- Neurogenic
  - Peripheral neuropathy (diabetes, alcoholism, uremia, Guillain-Barré syndrome, amyloidosis and the like)
  - Primary autonomic failure
    - Central—multiple systems atrophy (Shy-Drager syndrome)
    - Peripheral—idiopathic orthostatic hypotension
  - Central nervous system or spinal cord disease (strokes, tumors, trauma)—rare
- Miscellaneous
  - Aging
  - Deconditioning (prolonged bed rest, space flight)
  - Pooling (pregnancy, varicose veins, vena caval obstruction)
  - Vasodilatation (intense exertion, heat exhaustion, fever)
  - Sympathicotonia (mitral valve prolapse, some cases of diabetes)

TABLE 2.—*Workup of Patients With Orthostatic Hypotension*

Routine Evaluation	*Additional Tests*
Document orthostasis	
Drug history	
Detect hypovolemia	
History (fluid loss, bleeding, thirst)	ACTH stimulation test
Physical factors (standing pulse increased, mucous membranes, stool Hemoccult)	
Laboratory studies (urine specific gravity and protein; blood urea nitrogen and creatinine; serum sodium and albumin)	
Assess neurologically	
Peripheral	
Physical factors (vibratory sensation, reflexes)	Nerve conduction studies
Laboratory studies (blood glucose)	Hemoglobin A_{1c} Rectal biopsy
Autonomic	
History (incontinence, impotence, anhidrosis)	Cold pressor test Plasma norepinephrine level
Physical factors (standing pulse not increased, Valsalva)	
Central	
Physical examination (corticospinal, cranial nerves, extrapyramidal, cerebellar)	Computed tomographic scan (if CNS signs on exam)
Consider miscellaneous causes	
History (aging, bedridden, exertion, heat)	
Physical factors (pregnancy, varicosities, mitral valve prolapse)	Echocardiogram

ACTH = adrenocorticotropic hormone, CNS = central nervous system

Miscellaneous causes include aging, deconditioning, pooling, vasodilatation and sympathicotonia. Among persons older than 65 years, 10% to 24% have at least a 20-mm-of-mercury drop in systolic pressure with standing. Deconditioning refers to the baroreceptor disuse that may occur in settings such as prolonged bed rest and space flight. Pooling stems from the impedance to venous return found in conditions such as pregnancy, varicose veins and vena caval obstruction. Vasodilatation that accompanies strenuous exertion, heat exhaustion and fever may produce orthostasis. Sympathicotonia is a poorly understood entity of altered autonomic function characterized by decreased parasympathetic or increased sympathetic tone, or both. This has been postulated as a cause of the orthostatic hypotension that may occur in 10% to 15% of patients with mitral valve prolapse, supported by the improvement in their orthostasis with β-blocker therapy. A similar hyperadrenergic state may produce orthostasis in certain patients with diabetes mellitus, although hypoadrenergic hypotension due to peripheral neuropathy is more common.

Diagnosis

The workup consists of documenting orthostatic hypotension, checking for treatable causes and doing a careful neurologic examination (Table 2).

Authors differ as to the best means of determining orthostatic changes in blood pressure. The pressure should probably be checked after the patient lies supine for several minutes and again after the patient stands for several minutes. Sitting is not enough, unless it produces diagnostic orthostatic changes by itself, or unless the patient is incapable of standing. Ironically, supine hypertension may be prominent, due to compensatory hormonal and volume adjustments mediated in part by the renin-angiotensin-aldosterone axis. A corollary is that before initiating therapy in a patient presumed to have hypertension, standing blood pressures should be determined.

Treatable causes are primarily volume depletion and taking drugs. Detecting hypovolemia due to gastrointestinal losses, sweating or hemorrhage is familiar to most physicians. The uncommon but readily treatable Addison's disease should be pursued with an adrenocorticotropic hormone stimulation test when the findings suggest volume depletion without an obvious cause. Drug taking will be detected by a careful history.

Third, assessing the peripheral, autonomic and central nervous systems is mandatory. Peripheral neuropathies are readily detected on physical examination or, in selected cases,

by nerve conduction studies. If present, the next step is measuring fasting and postprandial blood glucose levels. Glycosylated hemoglobin measurements or a glucose tolerance test can be used to detect less obvious cases of diabetes, although autonomic neuropathy usually occurs in a setting of long-standing, complicated disease. In a nondiabetic person, other causes of peripheral neuropathy must be considered, including alcoholism, amyloidosis and uremia.

Having excluded volume depletion, drugs or a peripheral neuropathy, we should consider a pure failure of the autonomic nervous system. Such patients may also complain of disturbances in bowel, bladder or sexual function or of decreased sweating. Indeed, impotence or incontinence may antedate the onset of orthostasis. Two bedside tests of autonomic function include the heart rate response to standing and that following the Valsalva manuever. Whereas hypovolemic patients have a reflex tachycardia on standing, those with autonomic failure are unable to raise their heart rate. Regarding the Valsalva maneuver, a normal person's pulse rate will rise during the maneuver and decline following it. The normal ratio of maximum pulse during the maneuver to minimum pulse afterwards is 1.25 or greater. A ratio of 1.0 or less is suggestive of autonomic insufficiency. A little more involved but still noninvasive procedure is the cold pressor test, wherein a patient's hand or foot is placed in an ice bath for 60 seconds; normally, the systolic pressure should rise at least 15 mm of mercury.

Should autonomic insufficiency be detected, a full neurologic examination looking for corticospinal, cranial nerve, extrapyramidal or cerebellar signs should be done. This is to separate autonomic failure of the central type (multiple systems atrophy) from the more common peripheral variant (idiopathic orthostatic hypotension). Those with central nervous system symptoms—parkinsonism being the most common—have a worse prognosis, with the average life expectancy following the onset of symptoms being seven years. The more common, purely peripheral form of autonomic neuropathy occurs in middle-aged or older patients, with a 4:1 male predominance. A computed tomographic scan of the head would be indicated primarily in the setting of abnormal findings on a neurologic examination to exclude the rare posterior fossa tumor or infarct causing orthostatic hypotension. Finally, if volume-mediated, pharmacologic and neurogenic mechanisms are excluded, miscellaneous factors such as aging, pooling, deconditioning, vasodilatation and sympathicotonia should be considered.

Treatment

Given an irreversible cause of orthostatic hypotension, therapy consists of prophylaxis, physical methods, volume expansion and vasoactive drugs.

Simple preventive measures begin with avoiding sudden standing. Once upright, flexing the calf muscles or walking to augment venous return is preferable to passive standing. Frequent, small feedings may occasionally be required, with heavier meals inducing significant blood pressure drops due to splanchnic diversion. Strenuous exertion, particularly in hot, humid weather, should be avoided.

Physical measures include elevating the head of the bed 20 to 30 cm (8 to 12 in). This activates the renin-angiotensin system resulting in compensatory volume expansion. Elastic custom-fitted garments can diminish venous pooling but may be subject to considerable variability in patient acceptance. These are not merely support hose, or even knee-high or thigh-length Jobst stockings, but rather graduated pressure garments that allow a gradient of counterpressure to be applied with maximal pressure at the ankles and slight pressure at the top.

Volume expansion begins with a liberal sodium intake of 150 mEq or more per day. Frequently, however, exogenous mineralocorticoids in the form of fludrocortisone (Florinef) acetate must be administered. The starting dose is 0.1 mg per day and may be increased by 0.1 mg per day each week up to 1.0 mg per day. The major complications include supine hypertension, edema, hypokalemia and, in a cardiac patient, congestive heart failure. The goal is not normotension. A standing systolic pressure of 80 to 90 mm of mercury is often sufficient because cerebral perfusion is maintained down to systolic pressures of 70 mm of mercury.

Although the standard of pharmacotherapy, a fludrocortisone regimen alone is frequently insufficient. Other drugs, though experimental and often disappointing, might be needed. Methylphenidate (Ritalin) hydrochloride at a dose of 10 mg one to three times a day may be tried, either alone or in cautious combination with a monoamine-oxidase inhibitor such as tranylcypromine sulfate. With these, the patient should be observed for severe hypertension in the recumbent position. Indomethacin given in doses of 25 to 50 mg three times a day meets with occasional success. Intranasal inhalation of vasopressin just before ambulating has been advocated and vasopressin has the relative advantage of a relatively brief duration of action of one to four hours. In some instances, β-blockers have been useful, particularly in sympathicotonic conditions such as mitral valve prolapse.

How Do Doctors Discuss Do-Not-Resuscitate Orders?

ANTHONY MILLER *and* BERNARD LO, MD, *San Francisco*

Although patient preferences are important in decisions about "do not resuscitate" (DNR) orders, little is known about how physicians discuss these orders with patients. We asked 15 physicians to simulate discussing such orders with a patient. We found a striking variation in whether physicians explicitly asked for patient preferences, how they described cardiopulmonary resuscitation (CPR) and its possible outcomes and whether they made a recommendation to the patient about DNR orders. There was no pattern to the different amounts of information presented about CPR. Physicians gave conflicting reasons for how they individualized discussions with patients. Awareness of such different behaviors may stimulate physicians to examine what they say to patients about this sensitive and important topic and why they say it.

(Miller A, Lo B: How do doctors discuss do-not-resuscitate orders? [Health Care Delivery]. West J Med 1985 Aug; 143:256-258)

Cardiopulmonary resuscitation (CPR) may not be appropriate when cardiopulmonary arrest is the expected result of a worsening clinical course. In such situations, a "do not resuscitate" (DNR) order may be indicated. Shared decision making by physicians and patients about DNR orders has been recommended in the medical literature[1,2] and by the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research.[3]* Little is known, however, about how physicians discuss DNR orders with patients. Physicians may find discussion about DNR orders difficult for several reasons. Some physicians may be reluctant to talk with dying patients or to share the decision-making power.[4] Other clinicians may equate talking about death with giving up or failing. Physicians may be unsure about which issues to discuss and how to discuss them. Also, they worry that discussions of limiting treatment will leave a patient with the discouraging message that "nothing more can be done."

To investigate how physicians explain CPR and DNR orders, we asked a group of physicians to simulate how they would discuss "do not resuscitate" orders with a patient who has metastatic breast cancer. The technique of simulated patient encounters has been used to study how physicians make decisions,[5] and case presentations have been used to study how they resolve ethical dilemmas.[6] We were particularly interested in how physicians describe cardiopulmonary resuscitation and its results, whether or not they make a recommendation to the patient and how they describe supportive care.

Subjects and Methods

We studied 15 general internists in the Department of Medicine at the University of California, San Francisco, School of Medicine. They were selected for their reputation for compassionate care of seriously ill patients. Ten physicians were faculty members and five were residents. One other physician was excluded from the study because he had difficulty answering the questions and felt his experience with DNR orders was limited.

One of us, a second-year medical student (A.M.), presented a standardized hypothetical case of a 65-year-old woman with carcinoma of the breast metastatic to liver, lung and bone that has progressed despite hormonal therapy and chemotherapy. Her pain was controlled with a regimen of oral analgesics, but she had progressive weakness and fatigue. She was alert and in reasonable spirits. In the past she had wanted to discuss options for her care.

The physicians were asked to speak to the interviewer and a tape recorder as if they were explaining CPR and DNR

CPR = cardiopulmonary resuscitation
DNR = do-not-resuscitate

orders to the patient. The interviewer did not simulate patient questions or responses. After the simulated discussion, the interviewer asked standard questions about what the physician usually said in discussing DNR orders with patients.

Although there was wide variation in individual responses, there was no systematic difference between residents and faculty. Therefore, we have combined our results for faculty and residents, except as noted. Similarly, because there was no systematic difference between simulated discussions and responses to direct questions, we have combined data from these two sources.

Results

All physicians asked the "patient" to participate in the decision about CPR. In all, 11 (73%) asked explicitly what care she wanted if her heart or lungs were to stop. The remaining physicians posed the issue indirectly by asking the patient for her wishes if she became "very ill" or "something catastrophic" happened. All physicians but one summarized the prior clinical course with the patient to put the discussion of DNR orders in context.

Twelve physicians (80%) described CPR, but their descriptions varied. All 12 described intubation, but only 6 mentioned chest compression and only one electroshock. Some of the physicians explained why they do not describe some aspects of CPR. Two said that most patients know what CPR is because it is portrayed on television. Another feared that describing CPR would frighten the patient.

Three physicians (all faculty) did not describe CPR. When asked if he describes it, one responded, "Are you kidding? Patients have enough things to worry about. They've got death to worry about and not our particular version of technocratic death."

Ten physicians (67%) described the possible outcomes of CPR, but again they varied in what they specifically mentioned. Eight physicians described intensive care, five mentioned death explicitly, four said that there would be no change in the underlying illness after successful CPR, three mentioned possible brain damage and two spoke of a prolonged stay in hospital. One physician mentioned intensive care because the patient might be frightened by being in the intensive care unit, but he did not mention brain damage because the patient would not be aware of it. When asked if she mentioned possible brain damage after CPR, another physician said, "That's a good thought. It's so common afterwards, but I don't think I have [mentioned it]." Physicians disagreed whether or not to mention death explicitly: 11 did not; of these, 5 believed it was clear to the patient from the context of the discussion that a person would die without CPR.

Eleven physicians (73%) tailored the description of CPR to fit the patient and her situation. Explanations of how to individualize discussions varied greatly. Three physicians would give *more* details about CPR if the patient indicated that she wanted CPR, to be sure that the patient understood what is involved. Conversely, two other physicians would give *less* description if the patient wanted CPR. One was reluctant to precipitate an overt disagreement with the patient, and the other did not want to appear to dissuade the patient from her preferences. Two doctors would give more details if they believed CPR would not be effective. Another physician would limit the description with patients who deny the situation or have trouble making the decision.

Seven physicians (47%) recognized that their presentation might be biased. One physician said that she usually has decided what is appropriate before she discusses DNR orders with the patient. If she feels that CPR is not indicated, she "stacks the cards" to favor that decision. Another physician described the process as "explaining to the patient what you want and getting the patient to ask for what you want." They worried that patients might insist on CPR against their judgment as physicians. One described the dilemma and his ambivalence:

> I have two biases. One is that the patient needs to be the one to make the decision as long as she's with the program. But interlaced with that is that if there is no hope, then I don't feel that I'm obliged to treat in a hopeless situation. And I'll usually let the patient override that, if the patient is with it. But I'd rather the patient agreed to a "no code." I try not to make my opinion known, so that the patient's decision is informed. But I think I may bias it by making CPR sound as gruesome as it really is. I don't think CPR is pleasant and wouldn't want my wife or parent to have it.

Seven physicians (47%) gave a recommendation to the patient about CPR. One physician explained that the patient depends on the physician's opinion, "just like you'd depend on a car mechanic. . . . But I make it clear that we'll follow the patient's wishes because it's her death." Another physician made clear recommendations, while giving the patient a choice, "My feeling about it is that, given that we can't do much about your breast cancer, we should just make you comfortable if you stop breathing or your heart stops. . . . We wanted to discuss this issue with you and see what your feelings and thoughts about this are." Another physician emphasized supportive care in giving his recommendation: "I think what we should do right now is concentrate on the things we can treat."

Supportive care was mentioned by all physicians during discussions of CPR. One physician emphasized the importance of making the discussion positive rather than sounding as if "I am withholding CPR from you." Specific types of supportive care mentioned were controlling pain, seeing the patient regularly, arranging for visiting nurses and other home care, letting the patient cry and holding the patient's hand. One physician gave the patient her home phone number and said that the patient would probably need to see her more frequently now. Four physicians said explicitly that further care would not be affected by the patient's decision about CPR.

In the simulated discussions, physicians used medical jargon that might not be understood by patients. Such phrases included "big intravenous lines," "oxygen exchange" and "something acutely happened." Other phrases used were general and possibly ambiguous, such as "heroic," "catastrophic," "sophisticated," "cardiac problems" or "respiratory distress."

Discussion

Mutual decisions by physicians and patients have become the ideal for medical decision making. In such shared decision

making, patients must be informed about and understand the nature of their illness, the proposed treatment, the likely outcomes and the alternatives.[3] We found striking variation in discussions with the patient about CPR. Descriptions of CPR and its outcomes varied greatly: almost all physicians mentioned intubation, whereas only two mentioned a long hospital stay. Given such variability, patients may not receive enough information about CPR to enable them to make an informed decision.

There was no consistent pattern regarding different information presented about CPR. For example, some physicians give more details when a patient favors CPR, whereas other physicians give more details when a patient is against CPR. Such discrepancies suggest that it may be helpful for physicians to analyze what they say about CPR and why they say it.

Physicians in this study realized that they can influence patient choices. Some acknowledged that their presentations made it difficult for the patients not to agree with DNR orders. They justified such influence by their belief that CPR was not medically indicated. However, apparently technical judgments that CPR is "futile" or that a case is "hopeless" may be confounded by a physician's implicit assumptions and values, which may differ from those of the patient.[7] One way to minimize the effect of such assumptions is to conduct rigorous studies of patient outcomes after CPR.[8] These studies may identify clinical situations in which CPR is ineffective and therefore need not be offered to a patient as a therapeutic option.

Other physicians in this study hesitated to make recommendations about CPR. They wanted to be sure the patient had a choice and feared they would impose their wishes on her. However, some patients want the physician to make a recommendation, rather than merely describing alternatives.[9] Moreover, a completely objective presentation is impossible, since assumptions and values cannot be avoided. One approach in making recommendations to patients may be for physicians to be aware of their biases and to state them explicitly, like the physician who said that he believed that relief of symptoms was the most appropriate goal of treatment.

Supportive care was considered an important topic in discussions about DNR decisions. Physicians feared that discussions of limiting care could cause patients to feel abandoned or to believe nothing more could be done. Several physicians emphasized that although the explicit purpose of the discussion was to learn the patient's wishes about CPR, a more important implicit purpose was to communicate caring and concern to the patient.

Our study has several limitations. The number of physicians studied is small, and our results may not hold for physicians in other clinical settings, such as nonteaching hospitals and physicians other than internists. The format of a simulated noninteractive discussion is artificial. It is not known how performance in this situation correlates with performance with actual patients. Some physicians may have spoken more technically to a medical student than they would have to a layperson. However, it is unlikely that physicians merely gave responses that they considered to be socially acceptable, since they made candid responses and unsolicited comments.

Several physicians spontaneously remarked that they had found participating in the study to be helpful. One physician commented that his training had given little attention to talking with terminally ill patients. "I had no idea what I was doing when I started. No one talked to me about all this; I just had to wing it. Now I know what sells, and that's what I do." Another physician said that he had never previously thought about what he said to patients concerning CPR and that the simulated case helped him to examine what he says.

We hope that this initial study will stimulate physicians and medical students to examine what they say to dying patients and to consider how their words affect their patients. Simulated discussions between physicians and dying patients may be a useful educational technique to improve the care of such patients.

Low Back Pain

JAMES B. REULER, MD, *Portland*

Low back pain is one of the most common and costly afflictions of our society. The majority of adults will have at least one episode of acute low back pain that will likely resolve regardless of treatment. Lumbar spine radiographs are overused and there is little scientific support for many of the therapeutic interventions advocated. Even for those patients with symptomatic herniated disc, only a small fraction will ultimately require surgical intervention.

(Reuler JB: Low back pain [Special Article]. West J Med 1985 Aug; 143:259-265)

Low back pain (LBP) is a problem frequently encountered by primary care and emergency room physicians. In the National Ambulatory Medical Care Survey, LBP was the number one symptomatic complaint expressed by patients 25 to 60 years old seeing office-based physicians,[1] and it is the most costly medical problem in our society for the age group 30 to 60 years.[2] Poor understanding of this common syndrome leads to overuse of resources and the prescription of poorly validated treatment methods. In this review I will cover those aspects of LBP that are germane to an internist's practice and will discuss surgical intervention only as it pertains to decision-making about referral.

Epidemiology

LBP is the most common cause of limitation of activity for those under 45 years of age and is surpassed only by heart disease, arthritis and rheumatism in the age group 45 to 64 years.[3] In all, 60% to 80% of the population will experience at least one episode of acute back pain,[4-6] and a prolapsed disc is second only to schizophrenia as the most frequent condition for which disability payment is allowed by the Social Security Administration in those under 40 years of age.[7]

LBP represents a major issue for industry, where it is second only to upper respiratory illness in accounting for lost time from work—93 million days annually.[8] In the state of Oregon, the back was the injured body part in 31% of all claims accepted by Workers' Compensation, a frequency 2.5 times greater than that of any other body area.[9] Of such injuries, 75% involve the age group 20 to 44 years and the average amount of time lost from work is 14 days.

Vocational factors implicated in workplace-related back pain include physically heavy work, static work positions such as sitting and driving, frequent bending and twisting, lifting and forceful movements, repetitive work and vibration.[8,10,11] At the Kodak Company, back pain developed in 35% of sedentary workers and 47% of manual material handlers, with only 15% of cases being related to a definite injury.[12]

Biomechanics

The lumbar spine consists of a series of motion units each having an anterior and posterior segment. The anterior segment, composed of two vertebral bodies and the intervertebral disc, bears weight and absorbs shock.[4] The posterior segment, consisting of the vertebral arches, transverse and spinous processes and the inferior and superior articular facets, protects the neural structures and directs movement of the unit in flexion and extension. The disc is composed of the nucleus pulposus and a circumferential, intertwining fibroelastic mesh, the annulus fibrosus, which attaches to the vertebral bodies and permits a rocker motion. The unit is stabilized by a series of ligaments that minimize shearing forces and the paravertebral muscle bundles that provide balance for the static spine and strength for the kinetic spine.

Several factors relate to the stress on the motion unit. Disc pressure reflects the response to shearing and rotational loads, abdominal cavity pressure supports the trunk anteriorly and the myoelectric back muscle activity balances the gravitational forces in upright posture and forward flexion. Using intradiscal pressure measurements, Nachemson has shown marked variations in forces in various positions and activities.[13,14] For example, when a person is lying supine in the semi-Fowler position, a force of 100 Newtons is exerted on the L-3 disc. A person sitting upright without support generates seven times this force and when the same person bends forward and rotates while holding a 10-kg weight, the force increases 20-fold.

Causes of Low Back Pain

Though most patients experiencing LBP will have benign, nonemergent mechanical problems for which specific diagnoses will not be made, it is imperative to consider other

HNP = herniated nucleus pulposus
LBP = low back pain

disorders that may appear to be back pain. These may be classified as infectious (pyogenic osteomyelitis, epidural abscess), inflammatory (spondyloarthropathy), metabolic (osteoporosis, osteomalacia, Paget's disease), neoplastic (metastatic, primary cord tumor) and visceral (abdominal aortic aneurysm, urinary tract infection, pancreatic disease).[15,16] It is not within the scope of this review to address every potential cause of back pain, but selective entities representing common problems or areas of confusion are highlighted below.

Intervertebral Disc Disease

Though most structures in the back have been assigned roles in the causation of back pain, the disc has been implicated, at least indirectly, as the primary agent. Among reasons are the observations that true herniation is preceded by attacks of back pain, intradiscal injection reproduces pain and the anatomic changes in the disc and annular ruptures are first seen at younger ages, the same time that LBP becomes a clinical problem.[17]

At autopsy, herniated nucleus pulposus (HNP) is seen in 15% to 30% of specimens and degenerative changes are observed in the motion segments of all persons over the age of 60 years.[18,19] With age, the meshwork of the annulus becomes fibrotic, lessening the recoil properties of the hydraulic mechanism. These changes, coupled with microscopic fracturing of the end plates and facets, reduce the overall torsional strength of the unit and its capacity to absorb energy. Although pain produced by true herniation impinging on the nerve root is easily understood, the role of the changing mechanical behavior of the disc, the alteration of the height and protrusion of the disc on other sensitive tissues is not well defined vis-à-vis LBP. These age-related degenerative changes are often present in the absence of LBP.

HNP is generally a disorder of younger people, most frequently involving the L5-S1 and L4-5 discs.[20,21] The classic syndrome contains the following features: leg pain is dominant, unilateral and in a sciatic distribution, often aggravated by coughing, sneezing and forward flexion; paresthesias are localized to a dermatomal distribution; positive tension signs are present, including straight-leg raising, crossed-straight-leg raising and bowstring; at least two neurologic signs are demonstrable, including muscle wasting, motor weakness, diminished sensation and diminished reflex, and a contrast study will be positive for disc herniation at a level corresponding to the clinical features.[22] Table 1 lists the findings in the three commonly encountered disc syndromes.

TABLE 1.—*Root Compression Syndromes*

L5-S1 Disc (S1 Root)
- A. Pain/numbness—Posterior thigh and leg; posterolateral foot, lateral toes
- B. Weakness/atrophy—Plantar flexion foot, toes decreased; atrophy posterior compartment
- C. Reflex—Depressed Achilles' reflex

L4-5 Disc (L5 Root)
- A. Pain/numbness—Posterior thigh, anterolateral leg, medial foot and great toe
- B. Weakness/atrophy—Dorsiflexion foot, toes decreased; atrophy anterior compartment
- C. Reflex—No change

L3-4 Disc (L4 Root)
- A. Pain/numbness—Posterolateral aspect thigh, across patella, anteromedial leg
- B. Weakness/atrophy—Knee extension weak; quadriceps atrophy
- C. Reflex—Depressed patellar reflex

Several pitfalls are inherent in the diagnosis of HNP. Other disorders may mimic some of the above features, and the straight-leg raising test, or one of its variants, manifested by radicular leg (not back) pain upon passive stretching of the sciatic nerve, is not specific to HNP. Though virtually all patients under age 30 with a symptomatic herniation will have a positive straight-leg raising (true-positive) test result, the majority of patients with a positive test do not have a disc herniation (false-positive).[21] Additionally, older patients with confirmed herniation or those with higher root lesions (above L5 root) may have negative straight-leg raising test results (false-negative). The neurologic findings should be used as guidelines only in identifying the level of involvement, because overlap in innervation may lead to misinterpretation. The sensory examination must be mapped carefully to distinguish dermatomal from nondermatomal impairments.

Ankylosing Spondylitis

Ankylosing spondylitis, an inflammatory arthropathy with a strong predominance in men, has an age distribution similar to that of HNP and mechanical LBP.[23] Suggestive historical features are an age of onset of less than 40 years, insidious onset, duration longer than three months, morning stiffness and improvement with exercise. Positive responses to four of these features have a 95% sensitivity and 85% sensitivity for the disease.[24] A past history of iritis would further heighten suspicion. Maneuvers to assess spinal mobility, chest expansion and sacroiliac joint tenderness may be useful,[25] though in a recent series these tests did not have any clinical value in helping to distinguish between ankylosing spondylitis and noninflammatory back disorders.[26] The diagnosis is confirmed by plain radiographs of the sacroiliac joints that show bilateral sclerosis. In most instances, a single anteroposterior view of the pelvis will demonstrate the abnormalities by the time the patient first seeks medical attention. Nuclide scintigraphy and computed tomography have been reported to be useful in reaching a diagnosis in suspected cases when plain films are not yet abnormal, but their operating characteristics remain to be defined. Though results of the human leukocyte antigen B27 study are positive in 90% of white Americans with primary ankylosing spondylitis, the test does not confirm or exclude the presence of the syndrome, the diagnosis of which must be based on radiographic findings.[27] Exercises and anti-inflammatory drugs are the mainstays of therapy.

Facet Arthropathy

The lumbar zygapophyseal (facet) joints, located posterior to the plane of the intertransverse ligament and innervated by the dorsal primary ramus of the spinal nerve, have been

implicated as a common cause of LBP that mimics HNP.[28] The pain in this syndrome is intermittent, exacerbated by extremes of sudden movement and associated with diffuse thigh pain, often terminating at the knee. Physical findings are limited to tenderness over the facet joints magnified by hyperextension. Intraarticular facet block done with fluoroscopic guidance may confirm the diagnosis and injection may provide relief in selected patients.[29,30]

Spinal Stenosis

The term spinal stenosis includes narrowing of the spinal canal, nerve root canals and intervertebral foramina, all of which cause nerve root entrapment.[31] All forms of stenosis are characterized by a shallow lateral recess, that area bordered anteriorly by the vertebral body, laterally by the pedicle and posteriorly by the superior articular facet.[32] Those with the spinal stenosis syndrome experience back pain, transient motor deficits, tingling and intermittent pain in one or both legs, worsened by standing or walking (neurogenic claudication) and relieved by sitting or squatting, in contradistinction to HNP. Objective neurologic signs are absent at rest but may be present upon examination after exercise.[33,34] The diagnosis may be confirmed by a computed tomographic (CT) scan and, in some patients, symptoms may be relieved by surgical correction.[34,35]

Myofascial Syndromes

Myofascial pain syndromes arise from trigger points, focal areas of hyperirritability located in skeletal muscle and fascia which, when palpated, produce referred pain to distant sites.[36] The characteristics of trigger points have been delineated and the resultant syndromes causing LBP, including the quadratus lumborum, iliolumbar and piriformis syndromes, have been described.[37-41] Pain and weakness are elicited by maneuvers that cause the involved muscle to contract. Effective treatment may result from application of vapocoolant spray, injection of local anesthetic into the trigger point or ischemic compression of the area.[36]

Fibrositis, a related and common form of nonarticular rheumatism, is characterized by ill-defined musculoskeletal pain—often worsened by stress, cold and exercise—depression, nonrestorative sleep, chronic fatigue and early morning stiffness, and a physical examination will show no abnormalities except for tender spots located over muscles and ligamentous bony insertions.[42,43] The cause of the syndrome is unknown and its effective treatment is difficult. Antidepressants, centrally acting muscle relaxants and local injections may be of benefit.

Clinical Evaluation

The evaluation of LBP focuses on the differential diagnosis discussed above. Known malignancy, a history of intravenous drug abuse and constitutional symptoms such as anorexia, weight loss and fevers suggest metastatic cancer, vertebral osteomyelitis or epidural abscess. Inquiry about other organ-specific symptoms may uncover a nonmechanical cause of LBP, particularly urinary tract infection.[16] Age greater than 60 years and corticosteroid use have associated osteopenia and resultant compression fractures as a cause of LBP. The character of the pain pattern may suggest one of the syndromes discussed above, and bowel, bladder or sexual dysfunction may be clues to central midline disc herniation, carcinomatous extradural cord compression or cord tumor. A past history of LBP and related interventions, disabilities and litigation aid in placing the problem in perspective and planning a management strategy.

The physical examination should include observation of gait, trunk mobility and deformities and inequality of leg lengths.[21] In addition to a detailed neuromuscular examination, abdominal and vascular evaluations should be included, particularly in the elderly and those with symptoms suggesting neurogenic claudication. Localization of trigger points may lead to immediate therapeutic intervention.

Lumbar Spine Radiography

LBP is the most frequent symptom leading to diagnostic roentgenograms in an ambulatory care setting, with an estimated 7 million films done annually in the United States at a cost of $350 to $500 million.[44,45] Lumbosacral radiography is the largest contributor to gonadal irradiation and, unfortunately, the majority of specific findings (osteophytes, narrowed disc space, spondylolisthesis) do not correlate with the presence of LBP or predict its cause.[46] LaRocca and Macnab showed that only 7% of 150 asymptomatic laborers over the age of 35 years had normal radiographs and that the prevalence of degenerative changes (84%), congenital anatomic variations (64%) or both (57%) was comparable to a similar group with LBP.[47]

Liang and Komaroff, applying a formal decision analysis, compared a strategy that included radiographs on the first visit for acute, uncomplicated LBP with one in which films were delayed four to eight weeks.[48] Using prior probabilities of diseases causing LBP that could be diagnosed radiographically (disc space infection, osteomyelitis) and for which a specific treatment was available, the former strategy led to a decrease in suffering of only 58 minutes while generating a tenfold increase in cost and radiation exposure. Clinical studies have confirmed the conclusion that lumbosacral spine roentgenograms are of negligible diagnostic value in otherwise healthy patients with LBP under age 60 unless major direct spinal trauma, malignancy or infection is a concern or the pain has persisted for more than six to eight weeks.[16,44,49,50] The benefit of having oblique lumbar radiographs in addition to a single frontal and lateral view is negligible.[44,45]

Management of Acute LBP

Acute LBP is a self-limited disorder, with 50% of patients pain-free by one week, 80% by two weeks and 90% by eight weeks regardless of therapy.[51] Although innumerable therapeutic modalities have been advocated, the rate of spontaneous resolution, the diverse causes of LBP and the difficulty in measuring the symptom, pain, represent problems in evaluating efficacy of a given therapy.[52-54] Deyo has recently reviewed these methodologic pitfalls.[55]

The supine position maintained during bed rest has a theoretical advantage for instances of disc protrusion, considering disc pressure measurements discussed above.[14] Whether bed rest is useful in other causes of LBP is even less clear. Bed rest for 7 to 14 days, using a firm mattress and keeping hips and knees flexed, is an appropriate trial, acknowledging that the recommendations for duration are entirely empirical.[21,56]

Bathroom privileges should be allowed since the contortions associated with use of a bed pan are discouraging and biomechanically counterproductive. Lifting, bending and prolonged sitting should be avoided.

Because postulated mechanisms for LBP of soft tissue or disc origin implicate an inflammatory response, an anti-inflammatory agent is recommended. None of the nonsteroidal anti-inflammatory drugs has been shown to be more effective than aspirin and all are more expensive.[21,51,55,57,58] Antispasmodics and muscle relaxants probably act more by a sedative effect than at a specific neuromuscular site, are expensive and, again, none has been shown to be clearly efficacious.[59-65]

In addition to aspirin in therapeutic doses and bed rest, we recommend local heat, using a moist, hot towel, or cold applications, using a small wet towel placed in the freezer until malleable; these are simple adjuncts having theoretical support.[66-68] The traditional traction apparatus using small weights does little more than keep the patient in bed, because it has been shown that at least 25% of body weight must be applied to even begin to lower intradiscal pressure.[21,51,55] Spinal manipulation, of which several methods are used, has also not been proved to be effective.[21,69-71] Most important is reassuring the patient that LBP is generally self-limited and the prognosis for return to usual activities is good.

Surgical Procedures

Failure of a conservative therapeutic program for acute back pain frequently leads primary care providers to consider orthopedic or neurosurgical referral. Unfortunately, expectations of the referring physician and patient are often unrealistic with respect to the success of surgical treatment for symptomatic HNP. Though details of various surgical procedures for the lumbar spine are not germane to this review, an understanding of the natural history of conservatively treated and surgically treated disc disease is important.

In general, acute cauda equina syndrome and major or progressive paralysis represent clear indications for surgical intervention.[21] Other indications are relative, and patient selection remains a most important determinant of outcome of surgical therapy.[21,72,73] Operative procedures should be reserved for patients with symptoms of sciatica and neurological findings on examination, who have continued problems after 6 to 12 weeks of conservative therapy.[21,74] The goals of operations for HNP are to relieve sciatic and low back pain and to improve physiologic function, employment status, social functioning and the ability to perform activities of daily living.[21] The younger the patient and the greater the degree of herniation seen during the surgical procedure, the more likely it is that the pain will be relieved. Complete relief of back and sciatic pain occurs in approximately 60% of operative patients, with sciatic pain being relieved more frequently than back pain.[75] However, long-term follow-up of patients with sciatica and neurological findings who did not undergo surgical procedures showed that 52% were without symptoms and an additional 27% had only mild symptoms.[76] Work capacity and activity restriction were also similar in surgically versus conservatively treated groups.[76] Additionally, up to 10% of patients having operations for classic, severe sciatica will have a negative exploration.[75] This group has the worst prognosis. In general, only about 20% of patients with herniated nucleus pulposus require surgical intervention.[21] Indications for chymopapain injection are similar to those for surgical intervention.[22,77-79] Response to injection may not be complete for up to six weeks, and failure of chymopapain therapy does not obviate a subsequent operation. The referring physician, surgeon and patient must discuss the expectations of surgical intervention and the limitations and risks of the planned procedure.[80]

Diagnostic Studies

If it is agreed that an operation should be offered to and accepted by the patient, further diagnostic studies are indicated, remembering that up to 30% of asymptomatic persons have myelographically proved disc herniations.[72,81] It is important to do further studies because the correlation between the predicted level of herniation based upon neurological deficits on examination and the level of herniation on study is only 50% to 60%.

Much controversy exists today as to whether metrizamide myelography or computed tomography is the method of choice to establish the diagnosis and location of lumbar disc herniation.[82] Myelography permits direct visualization of the lumbar and sacral nerve rootlets. It is often difficult, however, for the myelographer to distinguish between a bulging disc, which does not cause nerve root compression, and a herniated disc. Also, symptomatic lateral herniations, particularly at the L5-S1 level, may be missed with myelography.[83,84]

With high-resolution CT scanners, a noninvasive diagnosis of HNP is possible. In series comparing CT with myelography in evaluating HNP in patients who underwent surgical exploration, CT has been shown to be of equal accuracy.[84,85] CT is particularly useful in evaluation of the vertebral bodies, posterior elements and paravertebral soft tissue mass and is the most precise method for assessing spinal stenosis. Also, CT is more accurate in detecting lateral herniations.[84] However, other extradural processes, such as scars, masses and spondylosis, may mimic focal disc protrusion and, as in myelography, it may be difficult to distinguish true herniation from a bulging disc.

Presently, the choice of initial diagnostic method for evaluation of HNP remains one of opinion. Review of the clinical information with the radiological and surgical consultants is important in determining a diagnostic strategy. An unequivocally abnormal or unequivocally normal CT scan may obviate the need for myelography unless the clinical evaluation contradicts the CT findings.[84] If neither the CT scan nor the myelogram provide a satisfactory answer, CT and metrizamide myelography done concomitantly may give additional clarification of the anatomy.

In difficult situations where a strong functional component appears to be present in patients with symptoms and signs suggesting nerve root compression, differential spinal anesthesia may be useful. This procedure consists of an injection of saline followed by injection of increasing concentrations of procaine hydrochloride into the subarachnoid space, causing sympathetic, sensory and motor blockage. If pain is relieved with saline or not relieved despite administration of 1% procaine hydrochloride, a strong psychological component to the pain problem is suggested.[21]

Management of Chronic LBP

The management of a patient with chronic LBP is often a vexing problem for physicians.[86] These patients often fall into

the category of "undesirable," arousing animosity in, and the use of pejorative terms by, their physicians. As in other nonmalignant chronic pain syndromes, narcotic analgesics are to be avoided and alternative therapeutic modalities have been used, including biofeedback, acupuncture, transcutaneous nerve stimulation, implanted neurostimulators and ablative neurosurgical procedures, all with varying success and all fraught with methodologic problems.[55] For selected patients, trigger-point injections may provide relief. In smaller subsets of patients, epidural corticosteroids[87-89] and corsets or braces[21,51,55] may be beneficial.

For most patients, however, there is little specific that one can offer. Although psychological profiling may be of some use in predicting responses to surgical intervention,[90,91] it is counterproductive to attempt to assign patients to organic or psychogenic categories.[86,91,92] In contradistinction to the disease model, the learning model, in which illness is comprised primarily of behavior and chronicity insures the need for behavior change, provides a more rational view of the chronic pain syndrome.[93] It can be assumed that the longer the patient has pain, the more the psychological factors become important in influencing neurophysiologic mechanisms underlying pain behavior. In this context, symptoms are to the disease model as behavior is to the learning model. Using scales of reliability such as the Minnesota Multiphasic Personality Inventory does not help to distinguish patients with organic or psychological pain. Both groups have increased scores for hypochondriasis, depression and hysteria indistinguishable from those of psychoneurotic patients.[86] These observations underscore the point that it matters little whether or not pain is real, but identifying those factors that influence pain is critical. The concept of chronic pain programs utilizes the principles of behavior modification, with goals being to identify and eliminate positive reinforcers for pain behavior, increase physical activity and decrease drug usage. These programs require commitment and motivation on the part of the patient and family and considerable financial expenditure. The long-term results of such programs vary.[94,95]

For most patients with chronic LBP, education and an exercise program are the foundations of successful therapy. Exercises, which may begin after the acute exacerbation abates, aim to minimize lumbar lordosis, thereby decreasing subluxation of the overriding facet joints, to decrease shearing stresses, to widen the intervertebral foramina and to strengthen abdominal and spinal musculature. Several types have been advocated, including extension and lumbar isometric flexion exercises, but no single program has clear superiority over another.[4,96-98] One of the most successful and widely available back programs is the Young Men's Christian Association's Healthy Back Program.[99] This course, offered throughout the United States, consists of six weeks of twice-a-week sessions, each of which include relaxation exercises and an increasing sequence of limbering, strengthening and stretching exercises. The charge is nominal, and the skills learned are continued at home indefinitely to minimize chronic pain and prevent acute attacks of LBP. The details have recently been published in an inexpensive book.[100]

Disability

Because LBP is such an important malady in the workplace, the issues of disability and compensation frequently arise.[101] The statutory definitions of a compensable personal injury are that it was out of, and in the course of, employment and occurred accidentally.[102] In most cases, physicians have no role in these decisions except in clear instances of extreme force or overt trauma, a small fraction of the occupationally related LBP. A physician may attend to the degree and nature of the impairment—that is, an objective assessment of anatomical or functional loss. However, there are often no objective means by which to assess many forms of impairment, particularly in LBP, and to establish the point at which healing is complete.[103] Disability, the loss of capacity to engage in gainful employment owing to the impairment, is in large measure behavioral and its determination is an administrative decision.[103-105] Hadler has reviewed the major points of interpretation of Workers' Compensation Law as related to LBP.[102]

Prevention

Given the staggering costs in dollars and reduced productivity resulting from LBP, prevention must be a major focus. Pre-employment screening by x-ray studies is not useful for identifying workers at high risk.[106,107] A history of prior LBP, however, and inability to demonstrate an isometric lifting strength equal to that required for a worker's job may have greater predictive value.[108-110] The study of ergonomics, the science of energy utilization in the workplace, has led to recommendations that minimize risk of back injury, including use of substitution devices, such as hoists, cranes and dollies, improved equipment and task designs to decrease vibration and stress and variation of work practices.[111] These principles have also been incorporated into car seats, furniture and leisure-time equipment design.

Medical Practice Question

EDITOR'S NOTE: *From time to time medical practice questions from organizations with a legitimate interest in the information are referred to the Scientific Board by the Quality Care Review Commission of the California Medical Association. The opinions offered are based on training, experience and literature reviewed by specialists. These opinions are, however, informational only and should not be interpreted as directives, instructions or policy statements.*

Percutaneous Transluminal Coronary Angioplasty

QUESTION:

Is Percutaneous Transluminal Coronary Angioplasty (PTCA) considered accepted medical treatment?

OPINION:

In the opinion of the Scientific Advisory Panels on Chest Diseases, Internal Medicine and Radiology, single vessel and multi-vessel percutaneous transluminal coronary angioplasty (PTCA) is considered established medical practice for patients who have coronary artery atherosclerosis.

PTCA should be done on carefully selected patients by physicians specially trained in the procedure and in facilities where the training of the PTCA team has been approved by medical staff or other peer reviewers. A cardiac surgery team should be immediately available in facilities where PTCA is done, in the event of complications.

Open-Heart Surgery— An American Experience in Shanghai

ELIAS S. HANNA, MD; SAMI S. KABBANI, MD, *and* TALI T. BASHOUR, MD, *San Francisco*

It was a first in more than one way—the first time a foreign medical team was allowed to operate in Shanghai, the first time a coronary bypass operation was done in Shanghai and the first time an important Chinese official was operated on by foreign doctors on Chinese soil.

For our team, however, operating in a foreign country lagging behind in modern medical technology was not exactly a new experience. Established in 1974 by Elias S. Hanna, MD (presently Chief of the Department of Cardiac Surgery and Medical Director of the newly formed Western Heart Institute at St Mary's Hospital and Medical Center, San Francisco), the Hanna Foundation has, over the past six years, sponsored special medical trips to many Third World countries, including Taiwan, Sri Lanka, Iraq and Syria. The traveling medical team usually included two cardiovascular surgeons, two cardiologists, one anesthesiologist, one perfusionist, one respiratory therapist, one operating room nurse, one intensive care nurse, one catheterization laboratory technician and one biomedical engineer.

On each of these trips the American team worked closely with a counterpart team from the host country (usually in a university setting) for a period of two to three weeks, doing cardiac catheterizations and operating on 5 to 12 local patients with a variety of heart disorders, introducing as a by-product the latest methods related to the management of heart disease to the foreign land. The China trip was the latest of the Hanna team's ventures.

The idea of visiting China developed in September 1980 at the annual meeting of the International College of Surgeons and through correspondence with professors of surgery at the Shanghai Second Medical College. Approval for the trip had to be cleared through the proper Chinese authorities, and it was not until September 1981 that the final details of the trip were worked out.

The tour was to be arranged and the tour guides provided by the Chinese Youth Federation, which has the official function of handling group trips to mainland China and maintains an office in Hong Kong. The original plan called for working in three hospitals affiliated with the Shanghai Second Medical College, but the number was reduced to two for logistical reasons.

The scientific exchange program with the People's Republic of China has so far resulted in two trips of the heart team to China (October 1982 and October 1983), and a six-week visit was made by the Chinese cardiovascular surgical team to St Mary's Hospital and Medical Center as guests of the Western Heart Institute.

The 1982 Visit

We arrived in Shanghai, the most populated city in China (12 million), on the eve of October 31, 1982, and were well received at the airport by the Chinese officials.

In Shanghai we stayed at the Jing-Jiang, an old hotel that dates back to "colonial time," but which is still considered one of the best hotels in China. The hotel was modest by western standards. On the way to the hotel, we were given our first instructions by David, our tour guide whom we soon got to like very much: "Don't drink running water," he suggested. "Instead, drink Chinese tea." As though to prove his point, Chinese tea was available in each hotel room, served with every meal and was an essential part of conferences, discussions and work breaks. Chinese tea, we were told, "reduces weight" and "prevents cancer"! David went on: "Don't go out at night." "Don't use local Chinese money," but rather the "special paper money" obtainable at the hotel exchange desk and at special "friendship" stores attended by foreigners.

We left the hotel for an early morning stroll and were amazed at the sight of dozens of Chinese (mostly elderly) performing the classic Chinese sport, *Tai-Chi Chuan,* commonly known in the West as "shadow-boxing." It appeared to be a blend of Swedish exercises, karate movements and Indian yoga. We were told that the sport dates back to 500 AD and is still practiced by most Chinese. Besides helping persons attain a "healthier body and spirit," it is supposed to "cure" many chronic conditions such as hypertension, tuberculosis and paralysis.

Chinese dress was modest and clean but monotonous. Almost all men and women wore blue jackets and grey or blue pants. The people seemed healthy. Rarely did we encounter an obese person, and seldom did we notice bad teeth. They

seemed quite adjusted to order (waiting lines were commonplace) and minded their own business. Seldom were we considered a novelty, and never were we followed by crowds.

The first day (November 1) was spent visiting the Shanghai Second Medical College and the five hospitals affiliated with it. There are two western-style medical colleges in Shanghai and a third college confined to teaching traditional Chinese medicine.

After 1981 the Second Medical College went back to a six-year program. (This had been reduced to five during the Cultural Revolution of 1966 to 1973.) The Second Medical College hosts 3,500 medical students (about 500 per year) and has three-year postgraduate courses in all specialties (100 postgraduates a year), leading to a master's degree. Recently, a doctorate (PhD) degree has been added in some of the programs.

Affiliated to the Shanghai Second Medical College are five general hospitals: (1) Rui-Jin, 1,200 beds (general); (2) Third People's Hospital, 650 beds (general); (3) Xin-Hua Hospital, 600 beds (mostly pediatric); (4) Ninth People's Hospital, 500 beds (mostly dentistry), and (5) Bao Gang Hospital, 300 beds (mainly industrial injuries). During 1981, the five hospitals combined treated about 50,000 inpatients and 4,500,000 outpatients.

After a reception and tea session with the President of the University (Professor Lan Xi-Ch'un), we visited the first three hospitals, but later our work was confined to the first two.

We learned that in 1956 the first open-heart procedure was done in China under hypothermia. The Chinese then developed their own extracorporeal machine (the most recent being Shanghai Type III) and their own oxygenators. Then occurred the following milestones:

1966-1973
Cultural Revolution setback.

1972
Open-heart operations under acupuncture anesthesia.

1977
The Chinese developed a tissue bovine valve (and pericardial valves), which they still use.

1978
Counterpulsation was developed in China.

The hospital buildings seemed to be very old but clean and well organized. Equipment was scarce and to a large extent outmoded. Physicians' and nurses' gowns and bed sheets were clean, but sterile technique was not strictly observed—one could go into operating rooms with street clothes after donning cap, mask, gown and shoe covers.

Both Rui-Jin and Third People's hospitals were doing 20 open-heart operations per month. Most of these (70%) were operations for rheumatic valve disease. The rest were for congenital or vascular disorders. Third People's Hospital seemed to be better equipped for doing open-heart procedures than did Rui-Jin. Most children had their open-heart operations at Xin-Hua Hospital.

Rui-Jin Hospital has 1,200 beds and six operating rooms. The catheterization laboratory is only adequate for studies of the right side of the heart. The echocardiographic machine was out of order during our visits. Only two to three open-heart operations are done weekly, yet a hyperbaric operating room chamber is available, now used mostly for degenerative retinal diseases and a variety of medical conditions. The modestly equipped surgical intensive care unit (SICU) has three beds.

Third People's Hospital has 650 beds and handles as many as 3,500 to 4,000 outpatients a day. The cardiovascular surgical department has 50 beds and manages four open-heart operations per week. The three to four beds in the SICU are modestly equipped. The catheterization laboratory at this hospital is better equipped, with Japanese-made monitors and an x-ray machine, but still lacks cineangiography.

Zing-Hua Hospital is a large hospital that has 820 beds and handles 5,000 outpatients a day. Of its 1,100 staff, there are about 200 physicians and 600 nurses. Students from the Second Medical College make their clinical pediatric rotation at this hospital, which manages three to four congenital open-heart operation cases a week. There are 25 cardiovascular surgical beds and a 4-bed SICU.

All Chinese physicians and nurses have permanent government jobs, but with the low salaries of $100 to $150 per month they lack incentive. Many of the physicians speak some English, none very well. Many are well read, and most have a good idea about recent developments in heart surgery.

The second day (November 2) was spent opening cartons, distributing equipment and choosing patients for a surgical procedure. We took about two tons of equipment. Most of the "hardware" machines were loaned by the respective companies (cardiac monitors, respirators, recorders and the like). A vast amount of disposable equipment was taken to China and left there at the end of the trip. Operations done are outlined in Table 1.

Our cardiologists worked almost every day (mainly in the catheterization laboratory of Third People's Hospital). They relied on videotape angiography because no cine equipment was available.

General Notes on Chinese Medical Personnel in Both Hospitals

At Third People's Hospital, personnel were better motivated and generally more geared to taking care of cardiac patients than those at the other two hospitals.

Chinese physicians, nurses and technologists were courteous and willing to work hard and for long hours. They asked questions politely and rarely ventured to express their opinions. When they did, their comments were generally pertinent. Occasionally, their questions displayed a lack of knowledge of today's medicine. Just as occasionally, their comments indicated surprisingly advanced knowledge. All were eager to help and to take care of patients. Nurses and laboratory reports were generally reliable. Our tour guide commented, "You American doctors work very hard to take care of patients—just like Chinese doctors."

Conferences and discussions were given extra weight—

TABLE 1.—*Schedule of Open-Heart Operations Carried Out in November 1982 in People's Republic of China*

Oate	*Operation*	*Hospital*
Nov 3.	Aortic valve replacement	Rui-Jin
Nov 8.	Mitral valve replacement	Third People's
Nov 9.	Aortocoronary bypass	Third People's
Nov 10.	Mitral valve replacement	Rui-Jin
Nov 11.	Aortocoronary bypass	Rui-Jin

every case needed to be discussed at the "tea table" before the operation. Every day started with a joint conference of the two teams. Emphasis was also placed on eating every few hours, yet none of us gained weight, possibly because Chinese food is generally low in calories.

Video films were taken of two of the operations and physicians and nurses frequently took notes. The Chinese wanted to learn everything we had to offer. The Chinese heart-lung machine and bubble oxygenator are rough copies of our Sarns and Bentley.

Postoperative care was generally poor, mainly due to poor facilities. Moving patients from the operation room to the intensive care unit was a chore. The first and last cases turned out to have many postoperative problems that could have been avoided had the operations been done in the United States.

Surgeons seemed to be good with their hands but lacked basic skills in postoperative care. Nurses seemed to be hard-working and conscientious. Hardly any nurse spoke English.

General Notes on Facilities in Both Hospitals

Operating rooms. The operating rooms were very modest in general. Lights were poor and equipment was obsolete. Sterile technique was not strictly observed, although everything seemed clean and the rate of postoperative infections, we were told, was low. We had some trouble using the Chinese pump and connections.

Intensive Care Unit. A thoracic surgeon was in charge of the intensive care unit (ICU), which is rarely visited by cardiologists. At Rui-Jin, the ICU was technically fit to take care of one patient although it was originally designed for four. Local monitors did not work half the time. No facilities were available for modern IV lines. Respirators were rarely, if ever, used. Fresh-frozen plasma or platelet transfusions were not available. At Rui-Jin, the portable x-ray machine was about 50 years old. Because of poor ICU care, patients were left in the operating rooms for three to four hours after a heart procedure until they could be extubated before transfer to ICU. In the United States, patients are intubated in the ICU for about 24 hours.

Catheterization laboratories. Catheterization laboratories were deficient. Cine films were not used. Adequate resuscitation equipment was not available. These laboratories are run by radiologists.

General Comments on Chinese Patients

Chinese patients are very stoic. They do not complain much, but they do very little to help themselves and fail to adequately follow postoperative treatment instructions. We have not noticed the display of emotion by family members as is so common in other Third World countries.

Other Activities

During the first two weeks, we had time for the following sightseeing: a Shanghai boat ride, Westlake and Hang Zhou resort cities near Shanghai, a Buddhist temple, a pagoda, Westlake park and gardens, a goldfish lake, a silk factory, the Shanghai zoo, a bamboo factory, the Shanghai ballet *(Swan Lake)* and Dragon Springs. We also had a group picnic.

Scientific lectures included topics like coronary bypass operation accompanied by a movie film, the diagnosis and clinical manifestations of coronary artery disease and postoperative care. During a reception given by the President of Second Medical College, plans were made for further cooperation and an exchange program between St Mary's Hospital and Shanghai Second Medical College.

On the last day (November 13) we visited the following places: Palace of Heaven, Forbidden City, National Museum, Mao's Mausoleum, the Great Wall of China, the Summer Palace of the Ming Dynasty and the Burial Place of the Jing Dynasty.

The 1983 Visit

This second visit served to enforce both the spirit of friendship between American and Chinese team members and the expertise gained by the Chinese personnel during the first visit. It was clear to all of us that heart surgery in China had improved remarkably over one year. We were excited and satisfied by the thought that we had contributed positively to this progress. Our team performed several operations during this visit and the atmosphere was that of a routine working schedule. The Chinese had in the meantime acquired or replaced much essential equipment that was lacking or not operational just a year before. We were amazed to see how their industrial institutions had successfully copied many of our basic products including machines, supplies and supportive medical systems. But more significant was the air of confidence and improved technical skills that characterized our Chinese co-workers. Improved also was their use of the English language. Most of the negatives of the 1982 trip were eliminated or greatly alleviated in 1983. This certainly attests to the great potential the Chinese people have and to their determination to catch up with advanced western medicine and technology. Their glorious history leaves little doubt that they will be successful in their drive. A seven-member team from China visited us in San Francisco in May 1984 for six weeks, during which time they gained more experience in our open-heart methods and more knowledge and an understanding of our way of life. More trips by our team to China are planned.

Commentary

Some Facets of Alternative Medicine—Today and Yesterday

MICHAEL C. LIVINGSTON, MD, *Richmond, British Columbia*

With medical costs still rising relative to gross national product, certain observers have wondered whether such costs could be reduced by decreasing the number of practicing physicians.[1] Meanwhile, relatively less is known about the use of alternative health practitioners.[2]

On one day in February 1984 I examined three patients whose cases may shed some light on the problem of alternative practitioners. I see similar cases fairly frequently for I am a family physician who also sees referred patients with neck or back problems.

Brief Reports of Cases

Case 1

The patient, a 20-year-old North American-Chinese woman* who was currently unemployed, had been an exercise teacher at the YMCA.

In June 1983 she had had a sudden pain in her lower back, but had danced for an hour before stopping. She received medication from her family doctor and was advised to rest, being reassured that the pain would go away. When it continued, she was referred to a rheumatologist who diagnosed a "short right leg syndrome" and recommended raising the heel. The pain became worse. She consulted a physiotherapist at a sports medicine clinic, was given 16 electrical treatments but no education and with no improvement. She then turned to the alternative healers, making about 40 visits to three separate chiropractors over the next few months. The chiropractors said rather different things, but from one she had full-body x-ray studies that "revealed" the following: a high right pelvis, a low right shoulder, a high right ear, a displaced second cervical vertebra, another displaced vertebra at about T-10, a sacrum twisted to the left, and her left pelvis twisted to the front—oh yes, and a short right leg.

There were many differences among the various therapists concerning causes and management.

She was currently attending a chiropractor who "just touches your neck." He makes a "specially delicate adjustment." The adjustment was so delicate in fact that the patient would not let me examine her neck because I might disturb it.

Not being able to examine her, I spent additional time in educating, explaining the various factors that contribute to pain—injury, tension, posture, past and family experience, treatment and so forth. I tried to open her understanding, to show her that she was being programmed into "becoming a patient," just as Pavlov's dogs had been programmed to salivate. I offered to teach her an effective posture and a relaxation and exercise program she could do at home, if she wished to return for a second visit.[3]

Case 2

The next patient, a 56-year-old real estate agent,* four months previously had suffered her fourth (rather minor) motor vehicle accident and was apparently having severe low- and mid-back pain.

She had consulted her family physician, who had agreed with her going to a chiropractor. After three months her physician suggested a physiotherapist who seemed more helpful to the patient, but he went on holiday and his replacement made her feel worse. She also saw a podiatrist who said her feet were in terrible shape and her back would never be right until her feet were right. The patient then began seeing a reflexologist.

In effect, her condition was unchanged over 4½ months.

On examination there were minimal findings except for pain on hyperextension of the lumbar spine. She seemed basically to be suffering from tension, anxiety and depression—she cried a lot during her visit—and from a lack of understanding of the natural course of her injury and from overtreatment. The natural history of her problem was explained and she was shown basic flexion pelvic tilting exercises with instructions to increase these gradually over a month and to walk daily. I suggested that she attend fewer therapists.

Case 3

The third patient, a young guitarist, had had low back pain for two weeks, accentuated by sitting and forward and back bending. He had trigger points to the right of L-5 and in the right gluteus medius. His straight-leg raising was limited to

*This patient was referred by Peter Chang, MD, of Richmond, BC.

*This patient was referred by Don Stewart, MD, Vancouver, BC.

(Livingston MC: Some facets of alternative medicine—Today and yesterday [Commentary]. West J Med 1985 Aug; 143:269-270)

Dr Livingston is in private practice in family medicine, with special interest in back problems, in Richmond, British Columbia.
Reprint requests to Michael C. Livingston, MD, Suite 305, 7031 Westminster Highway, Richmond, BC, Canada V6X 1A3.

60 degrees on the right side. There were no neurologic abnormalities.

While I was discussing with him the natural history of his problem, showing him three basic back exercises and using one manipulation on the right side at the fifth lumbar level, he told me of his past experience.

Three years previously he had had a two-year episode of lower back pain. He spent 20 visits receiving ultrasound from a physiotherapist and then some 70 visits being adjusted by a chiropractor, who he thought was good. The chiropractor gave him little education and the patient had a very limited exercise program. The physiotherapist apparently had not attempted any education.

While on a musical tour, his back still somewhat sore, he was walking with his wife down a side street in Regina, Saskatchewan, when a large jackrabbit jumped up on the edge and bounded away along the sidewalk. "Something came back to me from my childhood and I started to chase after the jackrabbit. The rabbit turned sharply right, I tried to turn also, and slipped on the ground, landing on my back. I got up and the pain had gone."

The jackrabbit adjustment had succeeded where 20 physiotherapy visits and 70 chiropractic adjustments had failed.

Discussion

These cases suggest a certain difficulty in exact diagnosis and a confusion of treatment and overtreatment both from alternative healers—in this instance, chiropractors—and possibly from physiotherapists. The actual cost of such care may be considerable. While these anecdotal cases are few, such description remains valid.[4] Further, I have over the past 18 years, while examining more than 6,000 patients with back and neck problems, encountered numerous similar cases. "People" have been turned into "patients" whom a therapist then "heals." Too frequently, dependence has been nurtured and self-care not encouraged.

Some of the strengths and weaknesses of alternative medicine were discussed by the surgeon Sir James Paget in a classical lecture in 1867, "Cases That Bone-Setters Cure."[5]

He noted that manipulating joints sometimes helped.

> Cases of this kind are of frequent occurrence. To the bone-setter, every injured joint is "put out"; and the one method of cure is the wrench and the rough movements, by which it is said that the joint is "put in" again.
>
> Now, it would be of little use to us to estimate, even if it were possible, the quantity of mischief done by treatment such as this. It is more important to know and consider that it sometimes does good; that, by the practice of it, bone-setters live and are held in repute by the ignorant of all classes everywhere.

He observed further that, "The patients who are cured never cease to boast of their wisdom in acting contrary to authorized advice; but they who are damaged are ashamed of themselves, and hold their tongues." Paget well described the magical effect of the alternative healer:

> If nothing in it but its portion of the nervous system is in fault, this may be sometimes cured through influence on the mind. And so not only bone-setters, but the workers with Mesmerism, and tractors, and oils, and distant or superficial electricity, can sometimes cure hysterical joints: for the patients love to be cured with a wonder; and the audacious confidence of all these conjurors is truly wonderful.

Finally, he adjured physicians to "learn then to imitate what is good and avoid what is bad in the practice of bone-setters," advice that the medical profession largely ignored.

More than 100 years have passed and Paget's principles still hold good for the alternative healers of today. Chiropractors have replaced bone-setters. Other alternative healers flourish for the very reasons that Paget described. Four other reasons may attract patients to these healers.

First, there is today general confusion and suspicion about science and some of its frightening effects. The environment is being threatened, some foods contain additives, drugs are responsible for side effects as well as benefits and the nuclear threat looms above all.

Alternative healers offer simple solutions without the bother of making an exact diagnosis. They may emphasize health rather than the absence of disease.

Second, most diseases are self-limiting or chronic. All healers receive some undeserved credit for healing when actually they are overseeing the natural course of an illness.

Third, modern diagnosis may involve the use of expensive technology and admissions to hospital. Physicians may not be much increasing their own fees, but they do generate higher costs by their use of modern technology,[6] multiple referral and hospital care. Alternative healers treat primarily an ambulant population and rarely make an exact diagnosis, so they rarely require such aids. The general public is often unaware of the lack of standards among such healers.

Finally, alternative healers usually have limited treatment options. Therefore, they concentrate on the most important treatment option of all, the healer-patient relationship. They concentrate on listening, on direct touch and on convincing patients. Direct contact used to be foremost in classical medicine.

Today science may stand in the way of our personal communication with our patients, as Norman Cousins recently noted:[7]

> Every time you go to a referral or to a diagnostic machine and then a referral beyond the diagnostic machine, you are increasing the distance between yourself and the doctor who is such a powerful ingredient in helping set you right.

Could alternative healers despite their weaknesses be, in effect, showing the medical profession the path to more effective healing—direct communication with patients?

Demographics and Disease Prevalence of Two New Refugee Groups in San Francisco

The Ethiopian and Afghan Refugees

BRIGID R. McCAW, MS, MPH, *Berkeley, California, and* PAUL DeLAY, MD, DTMH(Lond), *San Francisco*

Of all the Ethiopian (N = 110) and Afghan (N = 59) refugees seen at the Refugee Screening Clinic at San Francisco General Hospital Medical Center between May 1982 and July 1983, most were young men and more than 80% of each group were unable to speak English. The most frequently noted medical conditions in both groups were pathogenic parasites, dental caries and skin disorders. Most had positive PPD tests, but only a few cases of class A or class B tuberculosis were found. Among the Ethiopians two active cases each of Plasmodium vivax *malaria and trachoma were diagnosed. Although a wide range of diseases were seen, most were common rather than exotic. In addition to the need for translators, traditional beliefs and customs must be sensitively considered when providing health care to these groups.*

(McCaw BR, DeLay P: Demographics and disease prevalence of two new refugee groups in San Francisco—The Ethiopian and Afghan refugees [Cross-cultural Medicine]. West J Med 1985 Aug; 143:271-275)

During the past ten years, nearly 1 million refugees have been admitted to the United States.[1] Most have come from Indochina, but since 1980 significant numbers of refugees from other troubled areas of the world have also resettled here. In this report we describe the demographic characteristics and health problems of two refugee groups new to the United States, the Ethiopians and the Afghans. Although the two groups differ in fundamental ways, they share the common experiences of being displaced from their homes, a lack of familiarity with Western culture and having many similar health problems.

Afghans represent the largest group of refugees in the world today.[1,2] As of June 1983, about 12,000 Afghans have come to the United States as refugees.[3] Ethiopians form the third largest group of refugees in the world.[1] As of October 1983, about 10,000 Ethiopians officially classified as refugees have been admitted to the United States.[3] In addition, an estimated 10,000 to 40,000 Ethiopians who are not officially classified as refugees are currently living in the United States. Both of these refugee groups have been resettled throughout the country but the largest percentage have settled in California. If the admissions ceiling for these groups remains constant, between 3,000 and 6,000 Afghan refugees and 2,500 to 3,000 Ethiopian refugees are expected to relocate in the United States each year.[4]

Ethiopian and Afghan refugees are allocated to various US areas based on previous family ties and current local refugee population densities. In San Francisco, the resettlement agencies set up initial appointments for the refugees at the Refugee Screening Clinic at San Francisco General Hospital Medical Center. More than 90% of the primary migrants receive evaluation at the clinic, which provides a central location for medical care. Interpreter services are available for all refugees during the initial medical screening and about four months of ongoing care.

The medical records of all Ethiopian (N = 110) and Afghan refugees (N = 59) who were seen at the Screening Clinic between May 1982 and July 1983 were reviewed. Demographic data and health information were obtained for all refugees. The health information included pertinent findings from the medical history and physical examination, a clinician's assessment of a refugee's medical condition and the results of laboratory tests (complete blood count, VDRL and examination of a stool specimen for ova and parasites). Puri-

Ms McCaw is a fourth-year medical student in the Joint Medical Program, University of California, San Francisco, School of Medicine, and University of California, Berkeley, and Dr DeLay is Assistant Clinical Professor, Departments of Family Practice and of Epidemiology and International Health, University of California, San Francisco, School of Medicine, and Director, Refugee Medical Clinic, San Francisco General Hospital Medical Center.

This project was carried out during a summer research assistantship sponsored by the Division of Family and Community Medicine at the University of California, San Francisco. Computer funds were supplied by the School of Public Health at the University of California, Berkeley.

ABBREVIATIONS USED IN TEXT
HBsAg = hepatitis B surface antigen
PPD = purified protein derivative

fied protein derivative (PPD) testing was routine for all refugees younger than 21 years. Those older than 21 either received a PPD or a recent chest x-ray film was reviewed. The number of medical problems per patient and referrals to other clinics and specialties were determined. Obstetric information was also obtained for women of childbearing age (16 to 45 years old).

For the Ethiopian data, significance was tested by doing a χ^2 and a Fisher's exact test and the level of significance was set at $P = .05$. Only frequencies and raw data are reported for Afghans due to their small number. Although the findings presented here are based on a small, nonrandom sample—the first 110 Ethiopians and 59 Afghans screened—it is hoped that this study may serve as a guide to the health problems that may be seen elsewhere in such refugee groups and that it will stimulate studies in other localities.

The Ethiopian Refugees in San Francisco

"War, drought, civil strife and oppression have driven more than 1 million people out of Ethiopia during the past six years."[1] Conditions in Ethiopia are severe; at birth, life expectancy for men is 37 years, for women, 40.1 years, and infant mortality is 155 per 1,000 (D. Rosenthal, "New Ethiopia Emerges From Feudal Shadow of King Solomon," *San Francisco Chronicle,* Aug 7, 1983, p A15). Most Ethiopian refugees are poor and uneducated and have fled to the neighboring countries of Somalia, Sudan and Djibouti (G. Klein, "Ethiopian Refugees' Rough Road to US," *Christian Science Monitor,* Dec 30, 1982, p 7, and D. Winder, "Surge of Ethiopian Refugees Threatens Horn of Africa," *Christian Science Monitor,* April 26, 1983, p 1).[5-7] Until recently, however, most of those who have entered the United States have been from the educated classes, having left Ethiopia primarily because of political persecution or civil war.[8] Most are adept at urban living and familiar with Western ways and medical care. Nonetheless, they face considerable problems of adjustment once they have arrived here. Recently, rural Ethiopians have also begun entering this country. They tend to have medical conditions that reflect a more impoverished background and they are less familiar with Western culture and medicine.[9]

Demographics

Of this group of Ethiopians, 76 (69%) are male and 34 (31%) are female. The mean age is 22.7 years and the range is from 6 months to 50 years old.

Marital status. In all, 14 (13%) of the refugees are children (0 to 16 years old) and, among the adults, 74 (77%) are single and 22 (23%) are married. Of Ethiopian women older than 16 years, 39% are married. In contrast, only 17% of Ethiopian men are married.

About 30% came to the US with their immediate families, ranging in size from three to seven members.

Of the 28 women of childbearing age (16 to 43 years of age), 22/28 (79%) had no children, 3/28 (11%) had one or two children and 11% had four or five. At the time of screening, four (14%) of the women were pregnant.

Country of first asylum. The earliest Ethiopian refugees who arrived in San Francisco had been living independently in countries of first asylum. Initially, many arrived from Italy. More recently, refugees have come from camps located in Sudan and Djibouti. The average time spent in a refugee camp or other country before entering the United States was 21 months and the range was from 3 to 82 months.

Language. In the context of the screening clinic, the ability to speak English was defined as the ability to communicate effectively with a clinician about health problems or concerns. By this criterion, 84% could not speak English. The most commonly spoken languages were Amharic, the national language (80%), Tigregna (66%), Arabic (42%), Italian (13%) and Somali (7%). Two or more languages were spoken by 60% of the refugees.

Health Problems

General. The average number of medical conditions per person was 3.3. The standard deviation was 1.46 and the range was from 0 to 8. This determination was made for each refugee by adding the number of positive results on laboratory tests, the number of medical problems noted by a clinician and various health conditions. There were no significant differences in the number of medical problems between sexes or among age groups. Table 1 shows the most frequent medical conditions. A discussion of selected medical problems follows.

Tuberculosis. The determination of tuberculosis status was based on PPD results and chest film readings when pertinent. Before January 1983, PPD testing was not routinely done on patients older than 21 years unless it was clinically indicated. Since that time, PPD testing has been done on all patients, and those with a positive result (greater than 10 mm at 48 hours) receive a follow-up chest x-ray film.

Of those for whom adequate information was available (N = 44), 30% had negative PPD tests; 57% had positive PPD

TABLE 1.—*Most Frequently Reported Medical Conditions of the Ethiopian Refugees (N = 110) Based on Physical Examination*

Condition	Number of Cases	% of Those Tested
Stool specimen positive for pathogenic parasites (N = 89)	34	38
Dental caries	37	33
Dermatologic diseases (mainly tinea)	34	31
Gastrointestinal complaints (including constipation, abdominal cramping, peptic ulcer disease)	28	25
Musculoskeletal complaints	23	21
Gynecologic problems (mainly dysmenorrhea)	9	32 (N = 28)
Pregnancy	4	14 (N = 28)
Refractive errors	14	13
Thyromegaly	14	13
Headaches	13	12
Ear disease	13	12
Trachoma, or history of trachoma	10	9
Respiratory tract complaints	10	9
Positive VDRL	8	7
Physiologic cardiac murmur	8	8
Tuberculosis, class A or B	6	5
Trauma	5	4

tests and a normal chest film; 11% had positive PPD tests, an abnormal chest film but no evidence of active disease (class B), and 2% had positive PPD tests, an abnormal chest film and evidence of active disease (class A).

Other conditions. Two cases of active malaria *(Plasmodium vivax)* were diagnosed. A history of malaria was reported by 36% of this group of Ethiopians. Thyromegaly was present in 14 (13%); 12 of the 14 cases were female. Essentially all of these cases were of iodine-deficient endemic goiter. Ten (9%) persons showed evidence of active trachoma or recent infection by *Chlamydia.* Both a slit-lamp examination of the cornea and tarsal plates and identification of inclusion bodies in scrapings of the conjunctiva are necessary to distinguish active from inactive trachoma.

One case each of shigellosis and gonorrhea was diagnosed. No cases of filariasis, onchocerciasis, leishmaniasis, schistosomiasis, cholera, yellow fever, typhoid, typhus, relapsing fever or Hansen's disease were identified. These conditions are all known to exist in Ethiopia and the surrounding countries.[9-11]

There were 28 women of childbearing age in this group. As noted previously, 4 (14%) of the women were pregnant at the time of screening. Of the 28 women, 3 (11%) indicated that they were using some form of birth control. When asked, 19 (70%) stated that they wanted gynecologic services, which included pelvic examinations, Papanicolaou smears, birth control counseling and evaluation of pelvic pathologic conditions.

Laboratory Findings

Stool specimen examinations. Stool specimens were submitted for ova and parasite testing by 81% of the Ethiopians. Pathogenic parasites were found in 38% of those tested. There were no differences between male and female refugees in frequency of positive stool results. However, there were significant differences ($P = .004$) between age groups: Ethiopians aged 0 to 10 years and 30 to 40 years had the highest frequency of positive results. The parasites identified are listed in Table 2. Due to cost constraints, generally only one stool specimen per refugee was examined. Pathogenic parasites would likely be found in a greater percentage of Ethiopians if two or more stool specimens were examined. Most of the patients were asymptomatic and were treated according to the protocols stated in *The Medical Letter* (January 22, 1982). The two cases of *Schistosoma mansoni* showed no evidence of hepatic injury, colitis or polyposis.

Serology. VDRL reactivity was tested in all Ethiopians older than the age of 12 years and 8% were reactive. There were no associated symptoms, thus these cases were classified as latent syphilis and treated according to standard protocol. There was no difference between male and female refugees in the frequency of positive VDRL results. Due to cost, this population was not routinely screened for hepatitis B surface antigen (HBsAg) and no one was found to have active hepatitis. A recent study has found the prevalence of the HBsAg carrier state among Ethiopians to be 8%.[12] Thus, screening of pregnant women and administering the combined hepatitis B immunoglobulin and hepatitis B vaccine to neonates would be advised.

TABLE 2.—*Pathogenic Parasites Found in Ethiopian Refugees*

Parasite	Number of Cases	% of Those Tested
Giardia lamblia	15	16
Hymenolepsis nana	9	10
Entamoeba histolytica	6	7
Strongyloides stercoralis	5	6
Hookworm species	4	4
Schistosoma mansoni	2*	2
Trichuris trichiura	1	1

*In addition, 1 patient had a history of disease.

TABLE 3.—*Most Common Referrals of Ethiopian Refugees to Specialty Clinics**

Service	Number of Patients	% of All Ethiopians
Ophthalmology	26	23
Dental	18	16
Gynecology	15	†
Family Planning	2	†
Tuberculosis	10	9
Orthopedics	8	7
Ear, Nose and Throat	7	6
Cardiology	6	5

*Less frequent referrals included endocrinology, neurology and gastroenterology
†Considering Gynecology and Family Planning specialties together, 60% of women aged 16 to 45 years were deferred.

Referrals

The majority (67%) of the Ethiopians received at least one referral to specialty clinics. The most common referrals are presented in Table 3.

Cultural Considerations

The strong cultural pride of the Ethiopians plus their traditions of courtesy and reserve may prevent them from asking questions when they do not understand what is being communicated. While many refugees can speak some English, their ability to discuss their health problems and to comprehend our medical explanations may be limited. Therefore, the need for translators is critical. Since many fled Ethiopia because of political repression, they may be fearful that what they disclose could jeopardize family or friends who remain at home. Thus, the assurance of confidentiality and a sensitivity to their beliefs and customs is vital when providing services to this population. Health providers should also be aware of the possible history of torture when evaluating the physical and mental health of this group. Several refugees showed physical evidence of torture, mainly scars as a result of second- and third-degree burns.

In general, Ethiopians are comfortable and familiar with the use of Western medicine for some diseases, such as antibiotics for venereal disease. Nevertheless, they often maintain their own traditional beliefs and habits in regard to other health problems, such as herbal remedies for parasites and scarification around the eyes as a treatment for trachoma.[13] The controversial practice of clitorectomies on young girls is still being done in Ethiopia and some of the surrounding countries. Likewise, removing the uvula from young children is a very common practice and was frequently seen in the Refugee Clinic. Uvulectomy is generally done by a village healer, presumably to prevent recurrent throat infections.[9]

The Afghan Refugees in San Francisco

In 1978, after a political coup, a large number of Afghans fled from their country. The subsequent invasion by the Soviet Union in December 1979 caused further refugee movement.[14] There are now more than 3 million Afghan refugees living outside Afghanistan—many in camps in Pakistan and others seeking shelter in Iran, Turkey, India and various countries of Europe.[7,15]

Usually, the first wave of refugees to arrive in the United States from a particular country is from the better educated, upper classes. This reflects both the US immigration policies and the greater ease with which these people can leave their own country.[16] In general, this trend seems applicable to the Afghan refugees screened at the San Francisco General Hospital Refugee Clinic.

Demographics

Of this group of Afghans, 38 (64%) are male and 21 (36%) are female. The mean age is 24 years old, ranging from 6 months to 62 years. Children between the ages of 0 and 10 years make up about 30% (17) of this group and 51% of the adults are between the ages of 20 and 40.

Marital status. More than two thirds of the Afghan refugees came to the US with members of their immediate family. Family sizes vary from two to seven, and the mean family size is four members. About half of the adults are married. Of the Afghan women older than 16 years, 83% are married. In contrast, 36% of Afghan men older than 16 are married.

There were 13 women of childbearing age, and 10 had children. The average number was 2.8, but the range was from 1 to 10 children. Of the 13 women, 5 said that they were using some method of birth control. No current pregnancies were diagnosed at the time of screening.

Language. Within this group of Afghans, 47 (80%) could not speak English. The most commonly spoken languages were Dari (34 [58%]), which is a dialect of Persian, and Pashto (24 [41%]), a language also spoken by Pakistanis in the southeastern part of the country.

Health Problems

General. The average number of medical conditions per person was 2.2. No medical problems were found in five persons (9%); four or five problems were found in nine (15%). The most frequent medical conditions reported by the clinicians are listed in Table 4.

TABLE 4.—*Most Frequently Reported Medical Conditions in the Afghan Refugees Based on Physical Examination (N = 59)*

Condition	Number of Cases	% of Those Tested or Examined
Dental caries	24	41
Dermatologic disorders (tinea, scabies, eczema)	22	39
Stool specimen positive for pathogenic parasites	16	36
Gastrointestinal disorders (including constipation, peptic ulcer disease)	14	23
Musculoskeletal complaints, pain	7	12
Refractive errors	6	12
Hypertension	5	9
Hearing deficits and/or speech disability	3	5
Headaches	3	5
Physiologic cardiac murmurs	3	5

No Afghans had active malaria or a history of malaria. No cases of dracunculiasis, filariasis, leishmaniasis, shigellosis, cholera, typhoid, typhus, Hansen's disease or trachoma were identified. All of these diseases are known to exist in Afghanistan.[17]

Tuberculosis. The tuberculosis status of this group of Afghans is as follows: 10 (17%) had negative PPD tests, 32 (54%) had a positive PPD test and a normal chest film and 3 (5%) had a positive PPD test and an abnormal chest x-ray film but there was no evidence of active disease (class B).

There were no cases of active (class A) tuberculosis. In 13 (22%), the tuberculosis status could not be determined from the medical record because of inadequate information.

A breakdown of tuberculosis status by age shows that 59% of those refugees younger than 20 years had positive PPD results, whereas in those older than 20 years, 97% had positive PPD results.

Stool specimen examinations. Of this group of Afghans, 51 (86%) were tested for ova and parasites. Pathogenic parasites were identified in 18. Two age groups had the highest frequency of positive stool specimens: those between 0 and 10 years, and those between 20 and 30 years old. The parasites that were identified are listed in Table 5. Hookworm species and *Strongyloides stercoralis,* which are endemic in Afghanistan, were not identified in this population.

Serology. VDRL reactivity was tested in those older than 12 years, who represented 69% of the Afghans. None were reactive. This population was not routinely screened for hepatitis B surface antigen.

Anemia. Values for hemoglobin, hematocrit and mean corpuscular volume were available for all but three Afghans. The most common abnormality, a low mean corpuscular volume or microcytosis, was noted in nine (15%) Afghans. This condition usually results from iron deficiency, thalassemia or a hemoglobinopathy. Further diagnostic tests were not done.

Referrals

Of this group of Afghans, 30 (51%) received at least one referral to specialty clinics. The most common referrals were made to dental, seven (12%); family planning or gynecology or both, seven (12%); ophthalmology, six (10%), and tuberculosis clinics, six (10%).

Cultural Considerations

As a Near East Muslim country, Afghanistan has a strong religious tradition. This heritage is important to most refugees. Other cultural values include the importance of the extended family; respect for the advice and decisions of elders; traditional male and female roles, and a sense of privacy and modesty, especially among the women. A sensitivity to these

TABLE 5.—*Pathogenic Parasites Found in the Afghan Refugees Screened*

Parasites	Number of Patients	% of All Tested (N = 51)
Ascaris lumbricoides	5	9
Giardia lamblia	5	9
Entamoeba histolytica	4	7
Hymenolepsis nana	3	5
Trichuris trichiura	1	2

beliefs and customs will greatly increase the effectiveness of those who provide services for the Afghans.[17,18]

Discussion

The majority of both the Ethiopian and Afghan refugees seen in San Francisco are young men. Whereas most of the Ethiopians are single adults, most Afghans have come to the United States with their families. More than 80% of each group cannot speak English, and the need for translators, especially in a medical setting, is critical.

Pathogenic parasites, dental caries and dermatologic disorders were the most frequently noted medical conditions in both groups. Most Afghans and Ethiopians had positive PPD tests, but there were few cases of class A or B tuberculosis. A third of the Ethiopians have a history of malaria although there were only two active cases. Similarly, 7% had a history of trachoma, but there were only two active cases. However, examination of the everted tarsal plate should be included in the routine examination of this population. No cases of malaria or trachoma were found among the Afghans. Gastrointestinal and musculoskeletal disorders were frequent in both groups; pregnancy and thyroid disease, particularly endemic goiter, were noted more frequently among the Ethiopians.

As is true with other recently arrived refugee groups, the Ethiopians and Afghans are often depressed and agitated as a result of being away from their country and culture and having experienced the loss of family and friends.[19] While the outward signs may be subtle or confusing, health care practitioners should take this into account when diagnosing and providing care for these populations.

Although a wide range of medical problems is seen in these two refugee groups, the problems are common rather than exotic and do not pose a public health hazard. The Ethiopians and the Afghans, with their unique histories and cultures, have much to contribute to the United States. A sensitive understanding of their particular health care needs and problems will ease their entry into our society.

Allergy Practice in California

Diagnostic and Therapeutic Methods Used by Allergists and Otolaryngologists

ABBA I. TERR, MD
San Francisco

ALEX WEISSKOPF, MD
San Mateo, California

ROBERT A. SPARACINO
San Francisco

In 1982 the Scientific Board of the California Medical Association (CMA) established an interspecialty subcommittee to assist the Scientific Advisory Panel on Allergy and the Scientific Advisory Panel on Otolaryngology/Head and Neck Surgery in responding to medical practice questions on a variety of controversial methods of diagnosis and treatment of allergic conditions. The subcommittee of three allergists and three otolaryngologists, board certified in their respective specialties, was charged with identifying the common ground and defining the differences between the two specialties on such questions as cytotoxic testing for food allergy, sublingual testing and treatment for food allergy, endpoint titration for the diagnosis of inhalant allergy, the radioallergosorbent test (RAST), provocative-neutralization techniques for food allergy and autogenous urine injections for allergy therapy. The subcommittee's work was an extension of an informal dialogue begun by the advisory panels in 1979. The opinions subsequently recommended by the subcommittee on these questions were reviewed and endorsed by the parent advisory panels and received final approval from the CMA Commission on Quality Care Review.

To prepare for its in-depth evaluation of the issues cited, the subcommittee felt it essential to determine the frequency with which some of the more controversial techniques were used. It was apparent at the outset, however, that no such information about the actual use of diagnostic and therapeutic methods by practicing physicians existed; the subcommittee therefore surveyed CMA members for this purpose.

Methods

A questionnaire was prepared requesting specific information about the frequency of the use of various methods, both established and controversial, in the diagnosis of allergic disease and in allergen immunotherapy. It was mailed in February 1983 to all members of the California Medical Association who designated their specialty as either allergy or otolaryngology/head and neck surgery. This survey included questions about training, board certification and practice characteristics.

Questions about each test and treatment procedure were designed to elicit an estimate of the percent of new patient allergy evaluations in which the test or treatment was used.

Results

Questionnaires were sent to 201 allergists and 586 otolaryngologists; replies were received from 103 (51%) and 186 (32%), respectively. In all, 79 otolaryngologists indicated that they do not treat allergic disease, so the results were based on the remaining 107 (18%) otolaryngologists.

Allergy Training and Board Certification

Residency, fellowship, preceptorship training and board certification of respondents are shown in Table 1. Of the allergists, 83.5% had one or more years of residency in either internal medicine or pediatrics and 71.8% had postresidency allergy fellowship training. Of the otolaryngologists, 94.4% had one or more years of residency in that specialty and 4.7% reported allergy fellowship training.

Regarding board certification, 75.7% of the allergists responding were certified by the American Board of Allergy and Immunology, a conjoint board of the American Board of Internal Medicine and the American Board of Pediatrics. Among the otolaryngologists, 97 (90.7%) were board certified in that specialty, but only one in allergy and immunology.

TABLE 1.—*Training and Board Certification of 103 Allergy and 107 Otolaryngology/Head and Neck Surgery (Oto/H&N) Respondents*

	Allergy Number (%)	Oto/H&N Number (%)
Residency and Fellowship		
Residency (1 or more years)		
Family Practice	4 (3.9)	1 (0.9)
Pediatrics	38 (36.9)	1 (0.9)
Internal Medicine	48 (46.6)	2 (1.9)
Oto/H&N	6 (5.8)	101 (94.4)
Other	7 (6.8)	5 (4.7)
Allergy Fellowship	74 (71.8)	5 (4.7)

(Terr AI, Weisskopf A, Sparacino RA: Allergy practice in California—Diagnostic and therapeutic methods used by allergists and otolaryngologists [Information]. West J Med 1985 Aug; 143:276-279)

A report of the Interspecialty Subcommittee of the Scientific Advisory Panels on Allergy and Otolaryngology/Head and Neck Surgery of the Scientific Board of the California Medical Association. Drs Abba I. Terr and John A. Metheny were co-chairs of the subcommittee; the other members were Roger M. Katz, MD; W. Hugh Powers, MD; Alex Weisskopf, MD, and Ned J. Whitcomb, MD. Mr Sparacino is manager of the Department of Specialty Sections and Scientific Programs, California Medical Association.

Reprint requests to Robert A. Sparacino, Department of Specialty Sections and Scientific Programs, California Medical Association, 44 Gough Street, San Francisco, CA 94103.

Practice Characteristics

On the average, the ratio of adults to children in allergy practice is 2:1 for allergists and 4:1 for otolaryngologists. There is a large variation within individual practices, and a few physicians restrict their allergy practice to a particular age group. For allergists, the mean number of new cases per week was 8.7 ± 5.4; for otolaryngologists it was 4.9 ± 5.1.

TABLE 2.—*Type of Disease Seen in Allergy Practice (% of New Allergy Patients)**†

	Allergy	Oto/H&N
Nasal	54.8 ± 18.5	82.5 ± 20.9
Asthma	31.2 ± 14.5	8.5 ± 12.0
Food allergy	8.4 ± 10.6	11.6 ± 14.9
Urticaria	6.1 ± 4.4	4.3 ± 5.9
Gastrointestinal	4.3 ± 8.3	3.5 ± 5.0
Chemical allergy	3.5 ± 7.2	3.1 ± 3.4
Other	4.6 ± 5.8	8.2 ± 13.6

Oto/H&N = otolaryngology/head and neck surgery

*Mean ± 1 standard deviation.

†Total percentage may be greater than 100% because some patients present with more than one disease.

Table 2 shows that nasal allergy is the most common type of disease seen by both groups, constituting approximately 55% of the cases seen by allergists and 83% by the otolaryngologists. Allergists see a considerably higher percentage of patients with asthma.

Diagnostic Tests

The immediate hypersensitivity skin test in which a cutaneous wheal and erythema appears 15 to 20 minutes after application of an allergen is well established in allergy diagnosis. Despite the long tradition of the test, different methods for applying the allergen are used in clinical practice. Table 3 shows the respondents' use of the prick (puncture), scratch, single-dose intracutaneous (intradermal) and serial endpoint titration methods for diagnosing inhalant and food allergy.

The RAST detects specific IgE antibodies in serum. Table 4 shows the usage of RAST in the diagnosis of allergy to inhalants, foods and other allergens such as venom, drugs or occupational allergens. Table 4 includes data on the use of total serum IgE in diagnosis.

Controversial methods are used by only a handful of the respondents, as shown in Table 5. The cytotoxic test is based

TABLE 3.—*Diagnostic Tests for Initial Workup—Skin Test Method**

Test	Specialty	Percentage of Patients 0%	1-5%	6-25%	26-50%	51-75%	76-100%

Oto/H&N = otolaryngology/head and neck surgery, RAST = radioallergosorbent test

*Figures are percent of respondents in each specialty reporting frequency of usage of each method identified in the first column. Total percentage may diverge from 100% because of rounding errors.

on changes in leukocyte morphology after in vitro exposure to food extracts. Provocation-neutralization techniques consist of exposing a patient to a test substance to observe the presence of subjective symptoms over a subsequent ten-minute period. The testing is done by either injecting a substance intracutaneously or subcutaneously, or by applying a drop sublingually. Measurement of wheal diameter following intracutaneous injection and the occurrence of objective physical findings are also noted at times, but subjective symptoms are the primary indications of a positive result.

Immunotherapy

Treatment of allergic disease usually requires a broad-based program of environmental precautions or restrictions, symptomatic medication and, in some cases, immunotherapy consisting of repeated injections of allergenic extracts. The questionnaire focused only on methods used for immunotherapy. Repeated subcutaneous injections for treatment of inhalant allergy is the preferred method used by both allergists and otolaryngologists and frequency of use appears to be similar. Injections to treat food allergy in addition to inhalant allergy is not in common use by these physicians (Table 6).

Sublingual administration of drops of inhalant, food or chemical extracts has been advocated as an alternative method of treating allergy. It is considered controversial because no scientific studies have been published showing that it is effective. It is clear from Table 6 that very few of the allergists and otolaryngologists surveyed in California use sublingual therapy.

Discussion

To our knowledge this is the first survey of allergy practice by allergists and otolaryngologists. It was restricted to CMA members, so the results may or may not reflect practices of nonmembers or of physicians in other specialties who include allergy in their practice.

Among the respondents, more than 75% of the allergists were certified by the American Board of Allergy and Immunology and more than 90% of the otolaryngologists were certified by the American Board of Otolaryngology/Head and Neck Surgery, indicating that the results of this survey reveal allergy practice methods used by physicians with documented proficiency in their specialties.

Skin testing is clearly the method favored by both groups of specialists for identifying specific allergens. The immediate wheal-and-erythema skin test procedure is well established as a reliable and useful test for detecting specific IgE-mediated allergies, and its rationale is consistent with current concepts of the pathophysiology of immediate hypersensitivity allergic reactions. Nevertheless, the procedure itself has never been standardized so various techniques are in use today. In general, for routine testing purposes allergists use a two-step procedure in which a cutaneous (prick or scratch) test is applied first, and for those allergens giving

TABLE 5.—*Diagnostic Tests for Initial Workup—Controversial Methods**

Test	Specialty	Percentage of Patients 0%	1-5%	6-25%	26-50%	51-75%	76-100%
Cytotoxic test—foods	Allergy	94	1	1	1	1	1
	Oto/H&N	85	10	3	0	0	1

	Oto/H&N	86	6	4	0	0	3
Subcutaneous provocation-neutralization	Allergy	95	2	1	0	1	0
	Oto/H&N	91	1	2	0	0	5
Sublingual provocation-neutralization	Allergy	94	2	1	2	1	0
	Oto/H&N	92	0	0	0	3	4

Oto/H&N = otolaryngology/head and neck surgery

*Figures are percent of respondents in each specialty reporting frequency of usage of each method identified in the first column. Total percentage may diverge from 100% because of rounding errors.

TABLE 6.—*Immunotherapy Treatment Method**

Test	Specialty	Percentage of Patients 0%	1-5%	6-25%	26-50%	51-75%	76-100%
Subcutaneous—inhalants	Allergy	2	3	8	19	19	49
	Oto/H&N	10	4	22	8	9	47
Subcutaneous—inhalants and foods	Allergy	91	2	2	2	0	2
	Oto/H&N	78	7	6	2	2	4
Sublingual—inhalants	Allergy	95	2	2	0	0	1
	Oto/H&N	85	7	3	2	0	3
Sublingual—inhalants and foods	Allergy	92	6	2	0	0	0
	Oto/H&N	86	9	4	0	0	1
Sublingual—inhalants, foods and chemicals	Allergy	96	2	1	0	1	0
	Oto/H&N	91	6	2	0	1	0

Oto/H&N = otolaryngology/head and neck surgery

*Figures are percent of respondents in each specialty reporting frequency of usage of each method identified in the first column. Total percentage may diverge from 100% because of rounding errors.

negative reactions by this method, an intracutaneous test using a single standard concentration of extract is then applied. Serial endpoint titration is the method preferred by otolaryngologists. It consists of intradermal testing of each allergen serially at increasing concentrations until a positive (endpoint) test occurs. Our survey showed that the skin testing procedures are used by both allergists and otolaryngologists frequently in the diagnosis of inhalant allergy, but much less frequently for food allergy.

RAST, although favored more by the otolaryngologists, plays a small role in practice, since about 80% of the otolaryngologists and 90% of the allergists use this test rarely or not at all for the diagnosis of inhalant and food allergy. There is a small group of otolaryngologists who use this technique frequently.

Patients with atopic allergy usually have high circulating levels of total IgE in the serum. Because total IgE measurement affords no information about specific sensitivities, it is not surprising that fewer than 20% of physicians in either specialty order this test for most of their patients.

The controversial diagnostic techniques of cytotoxic testing and provocative-neutralization testing are not used to any significant extent by either specialty surveyed.

Treatment methods for allergen immunotherapy are similar. Subcutaneous injections are used to immunize for inhalant allergy, and very few practitioners report using immunotherapy to treat food allergy. Questions about dosage, frequency of injections, duration of treatment and patient selection criteria were not addressed in this questionnaire. The sublingual method of immunotherapy cannot be considered a significant part of the armamentarium of these physicians.

Conclusion

CMA member allergists and otolaryngologists were surveyed in 1983 to determine the methods they use for the diagnosis and treatment of allergy. These specialists generally employ similar methods in the diagnosis and treatment of allergic disease. Both groups rely on skin testing to identify specific allergens and both use a form of "titration." The otolaryngologists prefer the more formal serial intracutaneous endpoint titration method, whereas the allergists use a simplified two-step cutaneous-intracutaneous procedure. RAST is more likely to be used selectively than routinely, as is total serum IgE. The controversial diagnostic techniques of cytotoxic testing and provocation-neutralization are clearly out of favor by both groups of specialists.

Medical Practice Question

EDITOR'S NOTE: *From time to time medical practice questions from organizations with a legitimate interest in the information are referred to the Scientific Board by the Quality Care Review Commission of the California Medical Association. The opinions offered are based on training, experience and literature reviewed by specialists. These opinions are, however, informational only and should not be interpreted as directives, instructions or policy statements.*

YAG Laser for Posterior Lens Capsules

QUESTION:

Is the use of the neodymium YAG laser for opening (disruption) posterior lens capsules after extracapsular cataract extraction considered accepted medical practice or is it considered investigational?

OPINION:

In the opinion of the Scientific Advisory Panel on Ophthalmology, the use of the neodymium YAG laser to open (disrupt) posterior lens capsules after extracapsular extraction is considered established medical practice. When used in the anterior segment of the eye, this procedure has been reported to be safe and effective, with an extremely low rate of complications. Indeed, because it avoids infection and other complications of conventional ocular surgery, this technique is considered a preferred alternative to surgical discission.

Although the procedure itself is considered accepted practice, not all YAG lasers have been approved by the Food and Drug Administration (FDA) for this purpose. Their use, therefore, is investigational.

Utah State Medical Association Annual Meeting

September 25-27, 1985

Westin Hotel Utah, Salt Lake City

Changes will continue to take place as "Medicine Moves Ahead in the Eighties." The meeting theme this year calls attention to the special Forum on Medical Issues which will bring together nationally prominent speakers to address issues in government, medical ethics, hospitals, and physician practice patterns.

Forum on Medical Issues

Thursday, September 26, 1985

(CME Credit 3 Hours)

Carolyne K. Davis, R.N., Ph.D.

Administrator of the Health Care Financing Administration (HCFA), Dr. Davis oversees the functions of the Medicare and Medicaid programs. HCFA helps to finance health care services for 50 million poor, elderly and disabled Americans with a budget over $90 billion in 1985.

Scott S. Parker, M.H.A.

Mr. Parker has held positions with health care institutions on both a state and national level. He is president of the American Hospital Association, a past member of the Board of Trustees, and past chairman of Associated Hospital Systems.

Ernlé W. D. Young, Ph.D.

Chaplain at the Stanford University Medical Center, Dr. Young is a senior lecturer on medical ethics. With a worldwide perspective, Dr. Young is well informed on ethical conflicts currently facing medicine.

Joseph F. Boyle, M.D.

Past president of the American Medical Association and Executive Director of ASIM. Dr. Boyle was chairman for the Health Agenda for the American People. A captivating speaker, Dr. Boyle brings to the forum the perspective of physicians and the challenges they will face in the modern medical marketplace.

Physician Reactor Panel

Following presentations by Forum speakers, questions and interaction with a physician panel will take place.

Panel Members:

Kim A. Bateman, M.D., practicing family physician and immediate past president of the Utah State Medical Association, member of the AMA Young Physicians Committee.

Alan R. Nelson, M.D., practicing physician in internal medicine, member of the AMA Board of Trustees and member of the Governing Council of the Institute of Medicine, National Academy of Sciences.

John C. Nelson, M.D., practicing obstetrician and gynecologist, member of the National Commission for review of the DRG System, member of a Steering Committee for the Health Agenda for the American People.

William D. Odell, M.D., professor of medicine and physiology, chairman of the Department of Medicine, University of Utah.

USMA House of Delegates

Wednesday, September 25, 1985

The House will commence with delegates meeting Wednesday morning for consideration of resolutions, reports and election of officers.

Reference committee meetings will also be held Wednesday morning followed by a luncheon for delegates.

Thursday, September 26, 1985

The House will reconvene to hear reports from reference committees and election results.

Special Events

Wednesday, September 25, 1985

The Hospital Medical Staff Section will meet prior to the USMA House of Delegates.

Luncheon with guest speaker:
John J. Coury, Jr., M.D.
Chairman, Board of Trustees
American Medical Association

Thursday, September 26, 1985

Luncheon with guest speaker:
Scott S. Parker, M.H.A., President
American Hospital Association

Presidents' Reception and Banquet
Lafayette Ballroom, Hotel Utah

Marketing Strategies for Private Practice

Friday, September 27, 1985

(CME Credit 2 Hours)

The business side of medical practice will be reviewed in a special AMA practice management seminar. You will learn practical ways to increase your patient load and maintain satisfaction with existing patients.

Seminar is useful for physicians just entering practice as well as those who are well established.

Course is limited to 50 participants. Cost: $75.00

Scientific Program

Friday, September 27, 1985

(CME Credit 3 Hours)

This exceptional half-day course provides a medical update on heart and vascular disease. The Scientific session is sponsored by Hoechst-Roussel Pharmaceuticals, Inc.

Cost Effective Use of Antimicrobials

Steven R. Jones, M.D.
Department of Medicine
Good Samaritan Hospital and Medical Center
Portland, Oregon

New Aspects of Treatment — Chronic Peripheral Vascular Disease

D. Eugene Strandness, M.D.
Professor of Surgery
University of Washington School of Medicine
Seattle, Washington

Use of Thrombolytic Therapy in Myocardial Infarction

William John Rogers, Jr., M.D.
Director, Myocardial Infarction Research Unit
UAB Medical Center
Birmingham, Alabama

Computer Workshops

Friday, September 27, 1985

(CME Credit 7 Hours)

Computer industry and American Medical Association surveys indicate that computer ownership by physicians will steadily increase throughout the 1980's. "User friendly" systems are rapidly developing that make office-based computer systems a necessity. USMA will present the second annual computer seminar all day on Friday, September 27. Cutting-edge information and outstanding teachers will be available for Utah physicians.

Topics will include:

Computers in Medical Practice: An Introduction
Physicians' User Panel Presentation
Computer Communication
Paperless Billing
The Paperless Office
Clinical Software
Computers in Medical Practice Made Easy
Integrated Academic Information Management System

Registration: No registration fee for USMA members
Nonmembers $50 • Thursday Luncheon $10 • Presidents' Banquet $50 per couple

For further information or registration material, please contact Utah State Medical Association, 540 East Fifth South, Salt Lake City 84102. Telephone (801) 355-7477.

October 19-20—**Passionate Attachments: The Essential but Fragile Nature of Love.** Continuing Education Seminars at Century Plaza Hotel, Los Angeles. Saturday-Sunday. 12 hrs. $175. Contact: Continuing Education Seminars, 1023 Westholme Ave., Los Angeles, CA 90024. (213) 475-8300.

October 25-27—**Child Abuse.** Institute for the Advancement of Human Behavior at Anaheim. Friday-Sunday. 15 hrs. $145-$225. Contact: IAHB, 4370 Alpine Road, #205, Portola Valley, CA 94025. (415) 851-8411.

October 25-29—**The Spine: Advanced Concepts and Techniques.** The Spine Study Group at Vacation Village Hotel, San Diego. Friday-Tuesday. Contact: Spine Study Group, PO Box 13185, San Diego, CA 92103. (619) 692-9115.

October 26—**Symposium on Infectious Disease: Diagnosis and Treatment in the Office Practice.** Center for Healthcare Communications at Hilton Hotel, Sacramento. Saturday. 6 hrs. Contact: Pamela Harvey, Center for Healthcare Communications, 420 Lexington Ave., #320, New York, NY 10017. (212) 210-8940.

IDAHO

August 15-17—**Sun Valley Emergency Medical Conference.** Sun Valley. Thursday-Saturday. Followed by a float trip on the Middle Fork of the Salmon River, August 18-20. Sponsors: Idaho Emergency Medical Services System; Idaho Chap, American College of Emergency Physicians; Idaho Chap, Emergency Nurses Assn; Idaho Committee on Trauma, American College of Surgeons; Rural Area Model System. Contact: Idaho EMS System, 450 W State St., Boise 83720. (208) 334-4245.

August 15-21—**Effective Diagnosis and Treatment of Infectious Diseases.** Middle Fork of the Salmon River, Idaho White Water Rafting. Thursday-Wednesday. 24 hrs. Cat. I. Sponsors: University of Arizona College of Medicine and Epic Medical Expeditions. Contact: Richard Paris, MD, PO Box 209, Sun Valley 83353. (208) 788-4995.

August 22-25—**Intermountain Dermatology Society.** Red Fish Lake Lodge, Idaho. Thursday-Sunday. 9½ hrs. Sponsor: University of Utah. Contact: C. David Hansen, MD, (801) 321-1100.

September 8-14—**Up-to-Date Cardiac Therapy.** Middle Fork of the Salmon River, Idaho White Water Rafting. Sunday-Saturday. 24 hrs. Cat. I. Sponsors: University of Arizona College of Medicine and Epic Medical Expeditions. Contact: Richard Paris, MD, PO Box 209, Sun Valley 83353. (208) 788-4995.

October 12-18—**Effective Diagnosis and Treatment of Infectious Diseases.** Salmon River, Idaho Sports Fishing. Saturday-Friday. 24 hrs. Cat I. Sponsors: University of Arizona College of Medicine and Epic Medical Expeditions. Contact: Richard Paris, MD, PO Box 209, Sun Valley 83353. (208) 788-4995.

MONTANA

October 3-5—**Montana Medical Association Annual Meeting.** Outlaw Inn, Kalispell. Thursday-Saturday. Contact: NNA, 2012 11th Ave., Ste. 12, Helena 59601. (406) 443-4000.

NEW MEXICO

Information, requests for accreditation and items to be listed should be sent to the chairman of the CME Committee, New Mexico Medical Society, 303 San Mateo NE, Suite 204, Albuquerque, NM 87108 at least two months in advance. For information on CME accreditation or on the CME requirements of the New Mexico Board of Medical Examiners, please write to the above address or call (505) 266-7868.

NOTE: Course information in the following listing is subject to change on occasion. Check with the sponsoring institution for current details.

September 12-14—**Concepts and Controversies in Perinatal Care.** Albuquerque. Thursday-Saturday. 13 hrs. AMA Cat. I. Contact: Office of CME, UNM School of Medicine, Albuquerque 87131. (505) 277-3942.

October 4-5—**Ophthalmology for Primary Care Physicians.** Albuquerque. Friday-Saturday. Marriott Hotel. 10 hrs. AMA Cat. I. Contact: Office of CME, UNM School of Medicine, Albuquerque 87131. (505) 277-3942.

October 10-12—**New Mexico Cancer Symposium: Current Concepts in Cancer Management for Practicing Physicians.** Albuquerque. Thursday-Saturday. La Posada de Albuquerque. 15 hrs. AMA Cat. I. Contact: St Joseph Cancer Center, Albuquerque 87102. (505) 848-8000.

October 11-12—**First Balloon Fiesta Lung Disease Conference.** Albuquerque. Friday-Saturday. Veterans Administration Medical Center Education Building. 9½ hrs. AMA Cat. I. Contact: NM Chapter, American Thoracic Society, 216 Truman NE, Albuquerque 87108. (505) 265-0732.

November 1-2—**New Mexico Pediatric Society Annual Meeting—Infectious Diseases in Children.** Ruidoso. Friday-Saturday. Inn of the Mountain Gods. 8 hrs. AMA Cat. I. Contact: NM Pediatric Society, Marilyn Stark, Executive Secretary, 7605 Mountain Rd. NE, Albuquerque 87110. (505) 293-1333.

November 15-16—**New Mexico Medical Society Interim Meeting.** Las Cruces. Friday-Saturday. Holiday Inn de Las Cruces. Contact: NM Medical Society, 303 San Mateo NE, #204, Albuquerque 87108. (505) 266-7868.

December 5-7—**New Mexico Chapter, American College of Physicians, and New Mexico Society of Internal Medicine**—Annual Meetings. Thursday-Saturday. Marriott Hotel, Albuquerque. 12 hrs. AMA Cat. I. Contact: Office of CME, UNM School of Medicine, Albuquerque 87131. (505) 277-3942.

OREGON

The following list of continuing medical offerings in the state of Oregon is compiled by the Oregon Medical Association's Council on Medical Education. If you wish to submit information regarding future postgraduate courses, please submit the information to James A. Kronenberg, Associate Executive Director, Oregon Medical Association, 5210 SW Corbett Ave., Portland, OR 97201, or phone (503) 226-1555.

MEDICAL GRAND ROUNDS

Douglas Community Hospital, 738 West Harvard Avenue, Roseburg 97470:

Every Monday, 12:30 p.m. Contact: Robert A. Driver, MD, Douglas Community Hospital, 738 West Harvard Avenue, Roseburg, OR 97470. (503) 673-6641.

Emanuel Hospital, 2801 N. Gantenbein Street, Portland 97227:

Every Friday, 8:00 a.m. to 9:00 a.m. **Medical Grand Rounds.** Contact: Philipa McClure, Emanuel Hospital, 2801 N. Gantenbein Street, Portland, OR 92227. (505) 280-3200.

CONTACT INFORMATION

OHSU-CME—Contact: Division of Continuing Medical Education, Oregon Health Sciences University, Portland, OR 97201. (503) 225-8700.

Good Samaritan Hospital and Medical Center, 1015 NW 22nd Avenue, Portland 97210:

Every Wednesday, 8:00 a.m. to 9:00 a.m. **Medicine Grand Rounds.** Nursing Education Building, Room 110. Contact: Department of Medicine, Good Samaritan Hospital and Medical Center, 1015 NW 22nd Avenue, Portland, OR 97201. (503) 229-7454.

Providence Medical Center, 4805 NE Glisan, Portland 97213:

WSMA

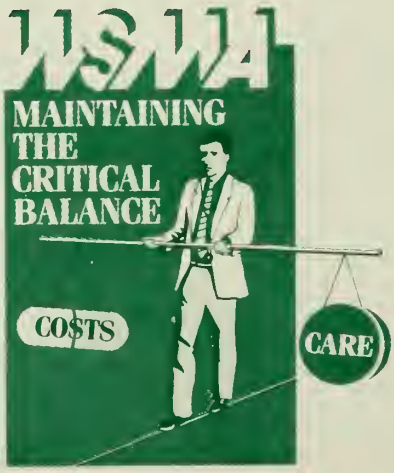
WASHINGTON STATE MEDICAL ASSOCIATION

MEETING FOCUSES ON CHANGE AND CHALLENGES

MAINTAINING THE CRITICAL BALANCE BETWEEN COSTS AND CARE will be an important theme of the 1985 WSMA Annual Meeting, September 19-22, Thunderbird Motor Inn, Jantzen Beach.

In addition to House of Delegates sessions which will shape future WSMA action on issues, including professional liability, the event-packed four-day meeting will feature a strong social-economic program and comprehensive scientific program.

All WSMA members are invited to attend.



ANNUAL MEETING
SEPTEMBER 19-22, 1985

SEPTEMBER 19-22, 1985

THUNDERBIRD MOTOR INN, JANTZEN BEACH, PORTLAND

SCIENTIFIC PROGRAMS

SURGERY	Prostate Imaging Using Transrectal Ultrasound, Plastic Surgery Symposium on Breast Reconstruction, Newer Aspects in Plastic Surgery
PSYCHIATRY	Post-traumatic Stress Disorder, Couples Therapy, WSPA Business Meeting
EMERGENCY MEDICINE	Chest Trauma in the Multiple Injury Patient, Post-Cardiac Arrest Cerebral Resuscitation, Thrombolytic Agents in Acute Myocardial Infarction, Free Standing Emergency Centers
ALLERGY	Recent Advances in Allergy and Clinical Immunology (for the non-specialist)
INTERNAL MEDICINE	Thrombolytic Therapy in Acute Myocardial Infarction, Update on AIDS, Pre-Thrombotic States and the Management of Venous Thrombosis, ACP: Health and Public Policy, ASIM Activities; An Update, Osteoporosis, Chronic Hepatitis, Flexible Sigmoidoscopy-1985, Ethics and Health Care Choices, Physician Reimbursement Issues, Rheumatology Session
OPHTHALMOLOGY	Scientific Program to be Announced, Choices for the Future of Ophthalmology, Joint Board Meeting (Washington and Oregon), Ophthalmic Assistants' Program (3 hour course on refraction)
FAMILY PRACTICE	Program to be Announced

A complete copy of the scientific program and annual meeting program is available from the Washington State Medical Association, 2033 Sixth Avenue, #900, Seattle, WA 98121, (206) 441-9762

Annual Meeting Speakers Varied, Provocative

An innovative no-fault approach to tort reform will be presented by Jeffrey O'Connell, professor of law at the University of Virginia. O'Connell specializes in accident and insurance law. He has authored numerous books including a 1979 work, "The Lawsuit Lottery: Only the Lawyers Win." O'Connell will speak to the House of Delegates on Thursday morning, 11:00 a.m.

Harry E. Morgan, Jr., chairman of the Health Care Purchasers Association of Puget Sound, will also address the House. He will discuss "A Business Prospectus on the Cost of Health Care."

Thursday afternoon Susan M. Schmidt, counsel to the special AMA Task Force on Professional Liability which has produced a series of reports on the issue, will join O'Connell and Morgan on a special reference committee panel. The panel will further review the liability issue and invite physician comment.

Dr. Roy M. Schwarz, AMA vice president of medical education and science policy, will address meeting attendees on Friday morning on the future direction of medical education and major science issues facing American medicine in the future.

Graham, Associate Administrator, San Luis Medical Clinic, Ltd., 1235 Osos St., San Luis Obispo, CA 93401; (805) 546-5600.

IDAHO: Eight-man group seeking ninth physician. Live near skiing, fishing, hunting, and wilderness while practicing in two modern medical centers. One is a trauma center with active EMS system. Seeking experienced EM physician, preferably with administrative experience and EM certification. Competitive salary, malpractice, retirement, and other fringes. Reply PO Box 2572, Boise, ID 83701 or call (208) 322-1730.

PHYSICIANS WANTED

GENERAL PRACTITIONER needed for hospital in Northern Oregon. A basic 40 hour work week, 8 am to 5 pm per day plus rotating emergency call will be required. Salary offered is $120,000 for the first 24 months. MD degree and one year medical internship required. Interviewing and moving expenses are paid. Qualified candidates please send CV to: Employment Division, Attn: Job Order #1885172, 875 Union St. N.E., Room 208, Salem, OR 97311. Job Order #1885172.

SAN FRANCISCO (San Francisco County): Internal Medicine private practice opportunity available. Board certified/eligible, woman preferred. Practice established over 8 years, busy, excellent location in office building next to Children's Hospital, with housestaff, ER, all facilities close at hand. Versatile call schedule and opportunities for teaching available. Contact: Ann Fricker, MD, 3838 California St., Ste. 12, San Francisco, CA 94118; (415) 387-6171.

OREGON—GENERAL SURGEON sought for multispecialty group, serving 57,000 population area. Beautiful rural community, 38 miles from Portland. Send CV to ADM. Physicians' Medical Center, P.C., 420 East 5th St., McMinnville, OR 97128; (503) 472-6161.

WESTERN U.S. OPENINGS

Several multi-specialty groups and clinics have asked us to recruit for over 100 positions of various specialties.

Western States Physician Search
240 West Shaw, Suite C
Clovis, CA 93612
(209) 297-7748

DEPUTY HEALTH OFFICER—An outstanding opportunity offering an expanded preventive and public health experience involving community health programs, outpatient care and participation in medical and health care management. Enjoy a semi-rural lifestyle, a reasonable cost of living, access to cultural amenities, a competitive starting salary, liberal fringe benefits, a regular schedule, and no overhead costs. Requires possession of a valid Physician's and Surgeon's Certificate issued by the State of California. Recruitment period: 6/24/85 to 8/30/85, 5:00 pm. Applications may be obtained by contacting the Butte County Personnel Department, 25 County Center Dr., Oroville, CA 95965-3387; (916) 534-4651. An equal opportunity employer.

GASTROENTEROLOGIST BE/BC wanted for large HMO practice in northern California wine country. Reply with CV to Box 6488, Western Journal of Medicine, 44 Gough St., San Francisco, CA 94103.

LOCUM TENENS

LOCUM TENENS SERVICE
WESTERN PHYSICIANS REGISTRY

. . . offers coverage for vacation or continuing education. To arrange coverage for your practice or to participate as temporary physician, contact: **Carol Sweig, Director, 1124 Ballena, Alameda, CA 94501; (415) 521-4110.**

SKI AND WORK—Part-time ER experienced, ACLS certified physicians sought to staff ski area clinics in Nevada, Oregon and New Mexico. Financial remuneration and benefits! Send CV to: C. H. Fagan, MD, Box 5220, Playa del Rey, CA 90296 or call (213) 546-3107 for further details.

PRACTICES AVAILABLE

CALIFORNIA BAY AREA. Primary Care for sale. Established General Practice one hour to San Francisco. Area growing very rapidly. $100,000+ gross last 5 years. Asking $50,000 but very flexible, depending on amt. of equip I leave. Please reply Box 6490, Western Journal of Medicine, 44 Gough St., San Francisco, CA 94103.

PULMONARY DISEASE/ALLERGY practice in San Bernardino. Good lease, 1,400-foot office. Computer billing and Video patient educational systems, Pulmonary Function Laboratory equipment, trained assistant. Donald Thornton, MD, 1800 North Western Ave., 3406, San Bernardino, CA 92411; (714) 887-8088.

WELL ESTABLISHED GENERAL PRACTICE and free standing care center in Northern California for sale. Office fully equipped. Inquiries Box 6481, Western Journal of Medicine, 44 Gough St, San Francisco, CA 94103.

PRACTICES AVAILABLE

OB/GYN PRACTICE for sale in the Napa Valley. Solo private practice with call sharing with other OB/GYNs. $300,000 gross in 1984. 150 bed hospital with new Maternity Center. One hour from San Francisco. Available immediately. Will continue working for three to six months to assure successful transition. Contact: Lanita C. Witt, MD, 935 Trancas, Suite 4E, Napa, CA 94558; (707) 257-2571.

OPHTHALMOLOGY PRACTICE FOR SALE: 1985 or 1986. Pacific Northwest Coast. Office building for lease or sale. Retiring. Will stay to introduce. Reply including CV to Box 6472, Western Journal of Medicine, 44 Gough St., San Francisco, CA 94103.

CALIFORNIA: Otolaryngology, Pediatric, Psychiatric, Opthalmology, Allergy, OBG, Family, Internal, Surgery, Orthopedic, others. Contact Mary Bradshaw, Practice Broker/Recruiter, 21 Altamount Dr., Orinda, CA 94563; (415) 376-0762.

ORTHOPAEDIC PRACTICE—Orange County, California, adjacent to major hospital; five additional hospitals in 5-mile radius; will aid in transition. Box 4191, Irvine, CA 92714.

SAN DIEGO—General Surgeon, OB/GYN, MD to take prac/office. Best med area. Off sublease. 2 cnslt 2 exam lg rcrds rm bath etc. Frn/equip avail. (619) 287-0151 or PO Box 202053, San Diego, CA 92120-0925.

REAL ESTATE

SAN LEANDRO: Prime, central. Prestige medical building. Ample parking. *Great* opportunity Internist or GP. Carol Bull, (415) 357-8940.

CENTRAL CALIFORNIA Arroyo Grande. Long term leasehold space with option to buy. 2,000+ square feet in new professional complex. Available in October. Help design interior now. Construction allowance given. (213) 649-0036.

AVAILABLE NOW—Oxnard, Ventura County, California; newly constructed 3,458 square feet with seven exam rooms, three consultation, x-ray, physical therapy, minor surgery, laboratory, nurses station. Contact: Anna Bischof, (805) 485-3193.

VALLEJO, CALIFORNIA: Prelease space in this new medical office building to be constructed across the street from Sutter Hospital. Sutter is doing a 13 million dollar expansion to the present hospital, to include 51 new beds, doubling the intensive care unit and adding to the surgery section. Marine World Africa USA is under construction within one mile bringing more growth to the area. Vallejo is halfway between Sacramento and San Francisco; it's convenient to skiing, the ocean and lake water sports. Building can be ready for occupancy in six months. Call Joe Lillis at (707) 864-8524 or write PO Box 523, Fairfield, CA 94533 for more information.

SITUATIONS WANTED

RADIOLOGIST SEEKS POSITION—41-year-old experienced Radiologist (academics and private practice) seeks multispecialty group, solo-type practice, or imaging center. Reply Box 6486, Western Journal of Medicine, 44 Gough St., San Francisco, CA 94103.

OFFICE SPACE AVAILABLE

OFFICE SPACE TO SHARE—Southern California area. Fully equipped and staffed medical office to share, in Los Angeles area. Office is 1,100 square feet, and includes x-ray and lab facilities. (805) 526-4380.

MISCELLANEOUS

CONTRACT NEGOTIATION: Practicing physicians with ten years' experience in collective bargaining and corporate medical affairs. Non-union. Call (415) 461-2080 for further information or write to PMC, Box 1434, Ross, CA 94957. Reply in strictest confidence.

New Prescribing Information

Now—Easier to remember... easier to prescribe

In place of Limbitrol 5–12.5 write:

Limbitrol®

Each tablet contains 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt) Ⓒ IV

In place of Limbitrol 10–25 write:

Limbitrol® DS

Each tablet contains 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) Ⓒ IV

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.

Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use, then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.

Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.) Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

***Usage in Pregnancy*: Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline, symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).

Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated; sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12. In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.

Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.

The following list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.

Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.

Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.

Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.

Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.

Endocrine. Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female, elevation and lowering of blood sugar levels, and syndrome of inappropriate ADH (antidiuretic hormone) secretion.

Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.

Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.

Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single *h.s.* dose may suffice for some patients. Lower dosages are recommended for the elderly.

Limbitrol DS (double strength) Tablets, initial dosage of three or four tablets daily in divided doses, increased to six tablets or decreased to two tablets daily as required. Limbitrol Tablets, initial dosage of three or four tablets daily in divided doses, for patients who do not tolerate higher doses.

How Supplied: *Double strength (DS) Tablets,* white, film-coated, each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt), and *Tablets,* blue, film-coated, each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 50.

Simple to take.

ROCHE®

in acute otitis media

- Penetrates and clears middle-ear fluid of susceptible strains of *H. influenzae* and *S. pneumoniae*[1]
- Reduces evidence of inflammation and bulging eardrum[2]
- Results in a reduction of fever, pain and other symptoms[2,3]

Active against 86% of *H. influenzae in vitro*—even amoxicillin- and ampicillin-resistant strains

Overall, 86% of *Haemophilus influenzae* strains taken from sputum cultures prove susceptible *in vitro* to Bactrim.[4] In one study, 100% of 191 ampicillin-resistant *H. influenzae* isolates were susceptible to Bactrim.[5] However, *in vitro* data do not necessarily correlate with clinical results.

Active against 91% of *S. pneumoniae in vitro*

In sputum cultures of *Streptococcus pneumoniae*, the most frequent pathogen in acute otitis media, 91% of isolates show susceptibility *in vitro* to Bactrim.[4]

Excellent clinical activity—and economical

In comparative clinical trials in children with acute otitis media, Bactrim *b.i.d.* was unsurpassed by ampicillin, amoxicillin or cefaclor.[6]
And the average cost of Bactrim is lower than that of cefaclor and comparable to that of ampicillin and amoxicillin.[7]
Bactrim is indicated in acute otitis media due to susceptible organisms when it offers an advantage over other antimicrobials. Bactrim is contraindicated in pregnancy, lactation, infants under two months of age and documented megaloblastic anemia due to folate deficiency. To date, there are limited data on the safety of repeated use of Bactrim in children under two years of age.

Cherry-flavored suspension

Bactrim™ Pediatric

(trimethoprim and sulfamethoxazole/Roche)

BACTRIM™ (trimethoprim and sulfamethoxazole/Roche)

Before prescribing, please consult complete product information, a summary of which follows:

Indications and Usage: For the treatment of urinary tract infections due to susceptible strains of the following organisms: *Escherichia coli, Klebsiella-Enterobacter, Proteus mirabilis, Proteus vulgaris, Proteus morganii.* It is recommended that initial episodes of uncomplicated urinary tract infections be treated with a single effective antibacterial agent rather than the combination. *Note:* The increasing frequency of resistant organisms limits the usefulness of all antibacterials, especially in these urinary tract infections.

For acute otitis media in children due to susceptible strains of *Haemophilus influenzae* or *Streptococcus pneumoniae* when in physician's judgment it offers an advantage over other antimicrobials. To date, there are limited data on the safety of repeated use of Bactrim in children under two years of age. Bactrim is not indicated for prophylactic or prolonged administration in otitis media at any age.

For acute exacerbations of chronic bronchitis in adults due to susceptible strains of *Haemophilus influenzae* or *Streptococcus pneumoniae* when in physician's judgment it offers an advantage over a single antimicrobial agent.

For enteritis due to susceptible strains of *Shigella flexneri* and *Shigella sonnei* when antibacterial therapy is indicated.

Also for the treatment of documented *Pneumocystis carinii* pneumonitis.

Contraindications: Hypersensitivity to trimethoprim or sulfonamides; patients with documented megaloblastic anemia due to folate deficiency; pregnancy at term; nursing mothers because sulfonamides are excreted in human milk and may cause kernicterus; infants less than 2 months of age.

Warnings: BACTRIM SHOULD NOT BE USED TO TREAT STREPTOCOCCAL PHARYNGITIS. Clinical studies show that patients with group A β-hemolytic streptococcal tonsillopharyngitis have higher incidence of bacteriologic failure when treated with Bactrim than do those treated with penicillin. Deaths from hypersensitivity reactions, hepatocellular necrosis, agranulocytosis, aplastic anemia and other blood dyscrasias have been associated with sulfonamides. Experience with trimethoprim is much more limited but occasional interference with hematopoiesis has been reported as well as an increased incidence of thrombopenia with purpura in elderly patients on certain diuretics, primarily thiazides. Sore throat, fever, pallor, purpura or jaundice may be early signs of serious blood disorders. Frequent CBC's are recommended; therapy should be discontinued if a significantly reduced count of any formed blood element is noted.

Precautions: *General:* Use cautiously in patients with impaired renal or hepatic function, possible folate deficiency, severe allergy or bronchial asthma. In patients with glucose-6-phosphate dehydrogenase deficiency, hemolysis, frequently dose-related, may occur. During therapy, maintain adequate fluid intake and perform frequent urinalyses, with careful microscopic examination, and renal function tests, particularly where there is impaired renal function. Bactrim may prolong prothrombin time in those receiving warfarin; reassess coagulation time when administering Bactrim to these patients.

Pregnancy: Teratogenic Effects: Pregnancy Category C. Because trimethoprim and sulfamethoxazole may interfere with folic acid metabolism, use during pregnancy only if potential benefits justify the potential risk to the fetus.

Adverse Reactions: All major reactions to sulfonamides and trimethoprim are included, even if not reported with Bactrim. *Blood dyscrasias:* Agranulocytosis, aplastic anemia, megaloblastic anemia, thrombopenia, leukopenia, hemolytic anemia, purpura, hypoprothrombinemia and methemoglobinemia. *Allergic reactions:* Erythema multiforme, Stevens-Johnson syndrome, generalized skin eruptions, epidermal necrolysis, urticaria, serum sickness, pruritus, exfoliative dermatitis, anaphylactoid reactions, periorbital edema, conjunctival and scleral injection, photosensitization, arthralgia and allergic myocarditis. *Gastrointestinal reactions:* Glossitis, stomatitis, nausea, emesis, abdominal pains, hepatitis, hepatocellular necrosis, diarrhea, pseudomembranous colitis and pancreatitis. *CNS reactions:* Headache, peripheral neuritis, mental depression, convulsions, ataxia, hallucinations, tinnitus, vertigo, insomnia, apathy, fatigue, muscle weakness and nervousness. *Miscellaneous reactions:* Drug fever, chills, toxic nephrosis with oliguria and anuria, periarteritis nodosa and L.E. phenomenon. Due to certain chemical similarities to some goitrogens, diuretics (acetazolamide, thiazides) and oral hypoglycemic agents, sulfonamides have caused rare instances of goiter production, diuresis and hypoglycemia in patients; cross-sensitivity with these agents may exist. In rats, long-term therapy with sulfonamides has produced thyroid malignancies.

Dosage: Not recommended for infants less than two months of age.

URINARY TRACT INFECTIONS AND SHIGELLOSIS IN ADULTS AND CHILDREN, AND ACUTE OTITIS MEDIA IN CHILDREN:

Adults: Usual adult dosage for urinary tract infections—1 DS tablet (double strength), 2 tablets (single strength) or 4 teasp. (20 ml) b.i.d. for 10-14 days. Use identical daily dosage for 5 days for shigellosis.

Children: Recommended dosage for children with urinary tract infections or acute otitis media—8 mg/kg trimethoprim and 40 mg/kg sulfamethoxazole per 24 hours, in two divided doses for 10 days. Use identical daily dosage for 5 days for shigellosis.

For patients with renal impairment: Use recommended dosage regimen when creatinine clearance is above 30 ml/min. If creatinine clearance is between 15 and 30 ml/min, use one-half the usual regimen. Bactrim is not recommended if creatinine clearance is below 15 ml/min.

ACUTE EXACERBATIONS OF CHRONIC BRONCHITIS IN ADULTS:

Usual adult dosage: 1 DS tablet (double strength), 2 tablets (single strength) or 4 teasp. (20 ml) b.i.d. for 14 days.

PNEUMOCYSTIS CARINII PNEUMONITIS:

Recommended dosage: 20 mg/kg trimethoprim and 100 mg/kg sulfamethoxazole per 24 hours in equal doses every 6 hours for 14 days. See complete product information for suggested children's dosage table.

Supplied: *Double Strength (DS) tablets,* each containing 160 mg trimethoprim and 800 mg sulfamethoxazole, bottles of 100, 250 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 20. *Tablets,* each containing 80 mg trimethoprim and 400 mg sulfamethoxazole—bottles of 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 40. *Pediatric Suspension,* containing 40 mg trimethoprim and 200 mg sulfamethoxazole per teaspoonful (5 ml); cherry flavored—bottles of 100 ml and 16 oz (1 pint). *Suspension,* containing 40 mg trimethoprim and 200 mg sulfamethoxazole per teaspoonful (5 ml); fruit-licorice flavored—bottles of 16 oz (1 pint).

SORBITRATE®
(ISOSORBIDE DINITRATE)

Please consult full prescribing information before use. A summary follows:

INDICATIONS AND USAGE: SORBITRATE (isosorbide dinitrate) is indicated for the treatment and prevention of angina pectoris. All dosage forms of isosorbide dinitrate may be used prophylactically to decrease frequency and severity of anginal attacks and can be expected to decrease the need for sublingual nitroglycerin.

The sublingual and chewable forms of the drug are indicated for acute prophylaxis of angina pectoris when taken a few minutes before situations likely to provoke anginal attacks. Because of a slower onset of effect, the oral forms of isosorbide dinitrate are not indicated for acute prophylaxis.

CONTRAINDICATIONS: SORBITRATE is contraindicated in patients who have shown purported hypersensitivity or idiosyncrasy to it or other nitrates or nitrites. Epinephrine and related compounds are ineffective in reversing the severe hypotensive events associated with overdose and are contraindicated in this situation.

WARNINGS: The benefits of SORBITRATE during the early days of an acute myocardial infarction have not been established. If one elects to use organic nitrates in early infarction, hemodynamic monitoring and frequent clinical assessment should be used because of the potential deleterious effects of hypotension.

PRECAUTIONS: General: Severe hypotensive response, particularly with upright posture, may occur with even small doses of SORBITRATE. The drug should therefore be used with caution in subjects who may have blood volume depletion from diuretic therapy or in subjects who have low systolic blood pressure (eg, below 90 mmHg). Paradoxical bradycardia and increased angina pectoris may accompany nitrate-induced hypotension. Nitrate therapy may aggravate the angina caused by hypertrophic cardiomyopathy.

Marked symptomatic, orthostatic hypotension has been reported when calcium channel blockers and organic nitrates were used in combination. Dose adjustment of either class of agents may be necessary.

Tolerance to this drug and cross-tolerance to other nitrates and nitrites may occur. Tolerance to the vascular and antianginal effects of isosorbide dinitrate or nitroglycerin has been demonstrated in clinical trials, experience through occupational exposure, and in isolated tissue experiments in the laboratory. The importance of tolerance to the appropriate use of isosorbide dinitrate in the management of patients with angina pectoris has not been determined. However, one clinical trial using treadmill exercise tolerance (as an end point) found an 8-hour duration of action of oral isosorbide dinitrate following the first dose (after a 2-week placebo washout) and only a 2-hour duration of effect of the same dose after 1 week of repetitive dosing at conventional dosing intervals. On the other hand, several trials have been able to differentiate isosorbide dinitrate from placebo after 4 weeks of therapy and, in open trials, an effect seems detectable for as long as several months.

Tolerance clearly occurs in industrial workers continuously exposed to nitroglycerin. Moreover, physical dependence also occurs since chest pain, acute myocardial infarction, and even sudden death have occurred during temporary withdrawal of nitroglycerin from the workers. In clinical trials in angina patients, there are reports of anginal attacks being more easily provoked and of rebound in the hemodynamic effects soon after nitrate withdrawal. The relative importance of these observations to the routine, clinical use of isosorbide dinitrate is not known. However, it seems prudent to gradually withdraw patients from isosorbide dinitrate when the therapy is being terminated, rather than stopping the drug abruptly.

Information for Patients: Headache may occur during initial therapy with SORBITRATE. Headache is usually relieved by the use of standard headache remedies or by lowering the dose and tends to disappear after the first week or two of use.

Drug Interactions: Alcohol may enhance any marked sensitivity to the hypotensive effect of nitrates.

Isosorbide dinitrate acts directly on vascular smooth muscle; therefore, any other agent that depends on vascular smooth muscle as the final common path can be expected to have decreased or increased effect depending on the agent.

Carcinogenesis, Mutagenesis, Impairment of Fertility: No long-term studies in animals have been performed to evaluate the carcinogenic potential of this drug. A modified two-litter reproduction study in rats fed isosorbide dinitrate at 25 or 100 mg/kg/day did not reveal any effects on fertility or gestation or any remarkable gross pathology in any parent or offspring fed isosorbide dinitrate as compared with rats fed a basal-controlled diet.

Pregnancy Category C: Isosorbide dinitrate has been shown to cause a dose-related increase in embryotoxicity (increase in mummified pups) in rabbits at oral doses 35 and 150 times the maximum recommended human daily dose. There are no adequate and well-controlled studies in pregnant women. SORBITRATE should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when SORBITRATE is administered to a nursing woman.

Pediatric Use: The safety and effectiveness of SORBITRATE in children has not been established.

ADVERSE REACTIONS: Adverse reactions, particularly headache and hypotension, are dose-related. In clinical trials at various doses, the following have been observed.

Headache is the most common (reported incidence varies widely, apparently being dose-related, with an average occurrence of about 25%) adverse reaction and may be severe and persistent. Cutaneous vasodilation with flushing may occur. Transient episodes of dizziness and weakness, as well as other signs of cerebral ischemia associated with postural hypotension, may occasionally develop (the incidence of reported symptomatic hypotension ranges from 2% to 36%). An occasional individual will exhibit marked sensitivity to the hypotensive effects of nitrates and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration, and collapse) may occur even with the usual therapeutic dose. Drug rash and/or exfoliative dermatitis may occasionally occur. Nausea and vomiting appear to be uncommon. Case reports of clinically significant methemoglobinemia are rare at conventional doses of organic nitrates. The formation of methemoglobin is dose-related and, in the case of genetic abnormalities of hemoglobin that favor methemoglobin formation, even conventional doses of organic nitrate could produce harmful concentrations of methemoglobin.

DOSAGE AND ADMINISTRATION: For the treatment of angina pectoris, the usual starting dose for sublingual SORBITRATE is 2.5 to 5 mg; for chewable tablets, 5 mg; for oral (swallowed) tablets, 5 to 20 mg; and for controlled-release forms, 40 mg.

SORBITRATE should be titrated upward until angina is relieved or side effects limit the dose. In ambulatory patients, the magnitude of the incremental dose increase should be guided by measurements of standing blood pressure.

The initial dosage of sublingual or chewable SORBITRATE for prophylactic therapy in angina pectoris patients is generally 5 or 10 mg every 2 to 3 hours. Adequate controlled clinical studies demonstrating the effectiveness of chronic maintenance therapy with these dosage forms have not been reported.

SORBITRATE in oral doses of 10 to 40 mg given every 6 hours or in oral controlled-release doses of 40 to 80 mg given every 8 to 12 hours is generally recommended. The extent to which development of tolerance should modify the dosage program has not been defined. *The oral controlled-release forms of isosorbide dinitrate should not be chewed.*

DOSAGE FORMS AVAILABLE: Sublingual Tablets (2.5, 5, 10 mg), Chewable Tablets (5, 10 mg), Oral Tablets (5, 10, 20, 30, 40 mg); Sustained Action Tablets (40 mg).

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g. chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD, IN GENERAL, NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery—Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia—Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis—Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Renal Function—Use nadolol with caution (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients—Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign of impending failure. Advise patients in event of missed doses.

Drug Interactions—Concurrent administration may result in interactions with: Anesthetics, general—exaggeration of the hypotension induced by general anesthetics (see WARNINGS, Major Surgery). Antidiabetic drugs (oral agents and insulin)—hypoglycemia or hyperglycemia; adjust antidiabetic drug dosage accordingly (see WARNINGS, Diabetes and Hypoglycemia). Catecholamine-depleting drugs (e.g., reserpine)—additive effect; monitor closely for hypotension and/or excessive bradycardia.

Carcinogenesis, Mutagenesis, Impairment of Fertility—In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy—In animal reproduction studies with nadolol, evidence of embryo-and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus. Neonates of mothers who received nadolol at parturition have exhibited bradycardia, hypoglycemia and associated symptoms.

Nursing Mothers—Nadolol is excreted in human milk. Exercise caution when nadolol is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular—Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System**—Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory**—Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal**—Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous**—Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision; infrequent reversible alopecia. The following adverse reactions have been reported in patients taking nadolol and/or other beta-adrenergic blocking agents, but no causal relationship to nadolol has been established. **Central Nervous System**—reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal**—mesenteric arterial thrombosis; ischemic colitis; elevated liver enzymes. **Hematologic**—agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic**—fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous**—pemphigoid rash; hypertensive reaction in patients with pheochromocytoma; sleep disturbances; Peyronie's disease. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia—Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure—Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension—Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm—Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; may be gradually increased in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 40 or 80 mg q.d. (doses up to 160 or 240 mg daily may be needed). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 40 or 80 mg q.d. (doses up to 240 or 320 mg daily may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and in Unimatic® unit-dose packs of 100 tablets. The 40 mg, 80 mg, and 120 mg potencies are also available in bottles of 1000 tablets. (J3-527D)

Issued: June 1985

Since with increasing blood pressure there may be a progressive decline in renal blood flow,[1] prescribe . . .

CORGARD® (nadolol tablets)

Lowers blood pressure

Preserves renal blood flow

Studies prove that CORGARD (nadolol tablets) preserves renal blood flow unlike some beta-blockers, such as propranolol.[1-4]

In a two-year study of 106 patients, CORGARD also decreased serum creatinine, a measurement of improved renal function.[5]

- *Offers once-a-day convenience.*
- *Low incidence of CNS side effects.**
- *Avoids potassium depletion.*
- *Maintains long-term control.*

CORGARD®
(nadolol tablets)

STEP-1 FOR HYPERTENSION WITH ONCE-A-DAY DOSE

*For a discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, please see brief summary of prescribing information on adjacent page.

TABLETS: 50 mg, 100 mg, 150 mg

DESCRIPTION

DESYREL® (trazodone hydrochloride) is an antidepressant chemically unrelated to tricyclic, tetracyclic, or other known antidepressant agents. It is a triazolopyridine derivative designated as 2-[3-[4-(3-chlorophenyl)-1-piperazinyl]propyl]-1,2,4-triazolo[4,3-a]pyridin-3-(2H)-one hydrochloride. DESYREL is a white odorless crystalline powder which is freely soluble in water. Its molecular weight is 408.3. The empirical formula is $C_{19}H_{22}ClN_5O \cdot HCl$.

INDICATIONS AND USAGE

DESYREL® (trazodone hydrochloride) is indicated for the treatment of depression. The efficacy of DESYREL has been demonstrated in both inpatient and outpatient settings and for depressed patients with and without prominent anxiety. The depressive illness of patients studied corresponds to the Major Depressive Episode criteria of the American Psychiatric Association's Diagnostic and Statistical Manual, III.[a]

CONTRAINDICATIONS

DESYREL is contraindicated in patients hypersensitive to DESYREL.

WARNINGS

TRAZODONE HAS BEEN ASSOCIATED WITH THE OCCURRENCE OF PRIAPISM. IN APPROXIMATELY 1/3 OF THE CASES REPORTED, SURGICAL INTERVENTION WAS REQUIRED AND, IN A PORTION OF THESE CASES, PERMANENT IMPAIRMENT OF ERECTILE FUNCTION OR IMPOTENCE RESULTED. MALE PATIENTS WITH PROLONGED OR INAPPROPRIATE ERECTIONS SHOULD IMMEDIATELY DISCONTINUE THE DRUG AND CONSULT THEIR PHYSICIAN.

Recent clinical studies in patients with pre-existing cardiac disease indicate that DESYREL may be arrhythmogenic in some patients in that population. Arrhythmias identified include isolated PVCs, ventricular couplets, and in two patients short episodes (3-4 beats) of ventricular tachycardia. Until the results of prospective studies are available, patients with pre-existing cardiac disease should be closely monitored particularly for cardiac arrhythmias. There have also been post-introduction reports of arrhythmias in DESYREL-treated patients, some of whom did not have pre-existing cardiac disease. DESYREL is not recommended for use during the initial recovery phase of myocardial infarction.

PRECAUTIONS

General: The possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Therefore, prescriptions should be written for the smallest number of tablets consistent with good patient management. Hypotension, including orthostatic hypotension and syncope, has been reported to occur in patients receiving DESYREL. Concomitant administration of antihypertensive therapy with DESYREL may require a reduction in the dose of the antihypertensive drug. Little is known about the interaction between DESYREL and general anesthetics, therefore, prior to elective surgery, DESYREL should be discontinued for as long as clinically feasible. As with all antidepressants, the use of DESYREL should be based on the consideration of the physician that the expected benefits of therapy outweigh potential risk factors. **Information for Patients**: Alert patients that (a) because priapism has been reported to occur in patients receiving DESYREL, patients with prolonged or inappropriate penile erection should immediately discontinue the drug and consult with the physician, (b) their mental or physical ability to perform potentially hazardous tasks, such as operating machinery or driving, may be impaired, (c) the response to CNS depressants such as alcohol or barbiturates may be enhanced, and (d) DESYREL should be taken shortly after a meal or light snack. **Laboratory Tests**: WBC and differential counts are recommended for patients who develop fever, sore throat or other signs of infection. Discontinue DESYREL if WBC or absolute neutrophil count falls below normal. **Drug Interactions**: Increased serum digoxin or phenytoin levels have been reported to occur in patients receiving DESYREL (trazodone hydrochloride) concurrently with either of those two drugs. Since it is not known whether an interaction will occur between DESYREL and MAO inhibitors, therapy should be initiated cautiously with a gradual increase in dosage until optimum response is achieved, if a MAO inhibitor is discontinued shortly before or is to be given concomitantly with DESYREL. **Therapeutic Interactions**: Concurrent administration with electroshock therapy should be avoided because of the absence of experience in this area. **Carcinogenesis, Mutagenesis, Impairment of Fertility**: No drug- or dose-related occurrence of carcinogenesis was evident in rats receiving DESYREL in daily oral doses up to 300 mg/kg for 18 months. **Pregnancy**: Since there are no adequate and well-controlled studies in pregnant women, DESYREL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus. **Nursing Mothers**: Since DESYREL and/or its metabolites have been found in the milk of lactating rats, caution should be exercised when DESYREL is administered to a nursing woman. **Pediatric Use**: Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS

Clinical Trial Reports: Side effects reported by more than 1% of the patients during clinical trials are the following. **Autonomic**—blurred vision, constipation, dry mouth. **Cardiovascular**—hypertension, hypotension, shortness of breath, syncope, tachycardia, palpitations. **CNS**—anger, hostility, confusion, decreased concentration, disorientation, dizziness/light-headedness, drowsiness, excitement, fatigue, headache, insomnia, impaired memory, nervousness. **Gastrointestinal**—abdominal/gastric distress, bad taste in mouth, diarrhea, nausea/vomiting. **Musculoskeletal**—musculoskeletal aches/pains. **Neurological**—incoordination, paresthesia, tremors. **Sexual Function**—decreased libido. **Skin**—allergic condition/edema, and **Other**—decreased appetite, eyes red/tired/itching, head full/heavy, malaise, nasal sinus congestion, nightmares/vivid dreams, sweating/clamminess, tinnitus, weight gain, weight loss. Side effects reported by less than 1% of the study patients are the following: akathisia, allergic reaction, anemia, chest pain, delayed urine flow, early menses, flatulence, hallucinations/delusions, hematuria, hypersalivation, hypomania, impaired speech, impotence, increased appetite, increased libido, increased urinary frequency, missed periods, muscle twitches, numbness, and retrograde ejaculation. **Post Introduction Reports**: Voluntary reports received since market introduction include the following: agitation, apnea, diplopia, edema, grand mal seizures, hallucinations, hemolytic anemia, liver enzyme alterations, methemoglobinemia, nausea/vomiting (most frequently), paresthesia, priapism (see PRECAUTIONS, Information for Patients, some patients have required surgical intervention), rash, weakness. Cardiovascular system effects which have been reported are the following: orthostatic hypotension and syncope, palpitations, bradycardia, atrial fibrillation, myocardial infarction, cardiac arrest, arrhythmia, and ventricular ectopic activity, including ventricular tachycardia (see WARNINGS).

OVERDOSE

Signs and Symptoms: Death from overdose has occurred in patients ingesting DESYREL (trazodone hydrochloride) and other drugs concurrently (namely, alcohol, alcohol + chloral hydrate + diazepam, amobarbital, chlordiazepoxide, or meprobamate). The most severe reactions reported to have occurred with overdosage of DESYREL alone have been priapism, respiratory arrest, seizures, and EKG changes. The reactions reported most frequently have been drowsiness and vomiting. Overdosage may cause an increase in incidence or severity of any of the reported adverse reactions (see ADVERSE REACTIONS).

DOSAGE AND ADMINISTRATION

The dosage should be initiated at a low level and increased gradually, noting the clinical response and any evidence of intolerance. Occurrence of drowsiness may require the administration of a major portion of the daily dose at bedtime or a reduction of dosage. DESYREL should be taken shortly after a meal or light snack. **Usual Adult Dosage**: An initial dose of 150 mg/day in divided doses is suggested. dose may be increased by 50 mg/day every three to four days. The maximum dose outpatients usually should not exceed 400 mg/day in divided doses. Inpatients may given up to but not in excess of 600 mg/day in divided doses. **Maintenance**: Dosage during prolonged maintenance therapy should be kept at t lowest effective level. Once an adequate response has been achieved, dosage may gradually reduced, with subsequent adjustment depending on therapeutic respon

HOW SUPPLIED

DESYREL® (trazodone hydrochloride) 50 mg and 100 mg scored tablets, and 150 m DIVIDOSE® tablets.

CAUTION: Federal law prohibits dispensing without a prescription.

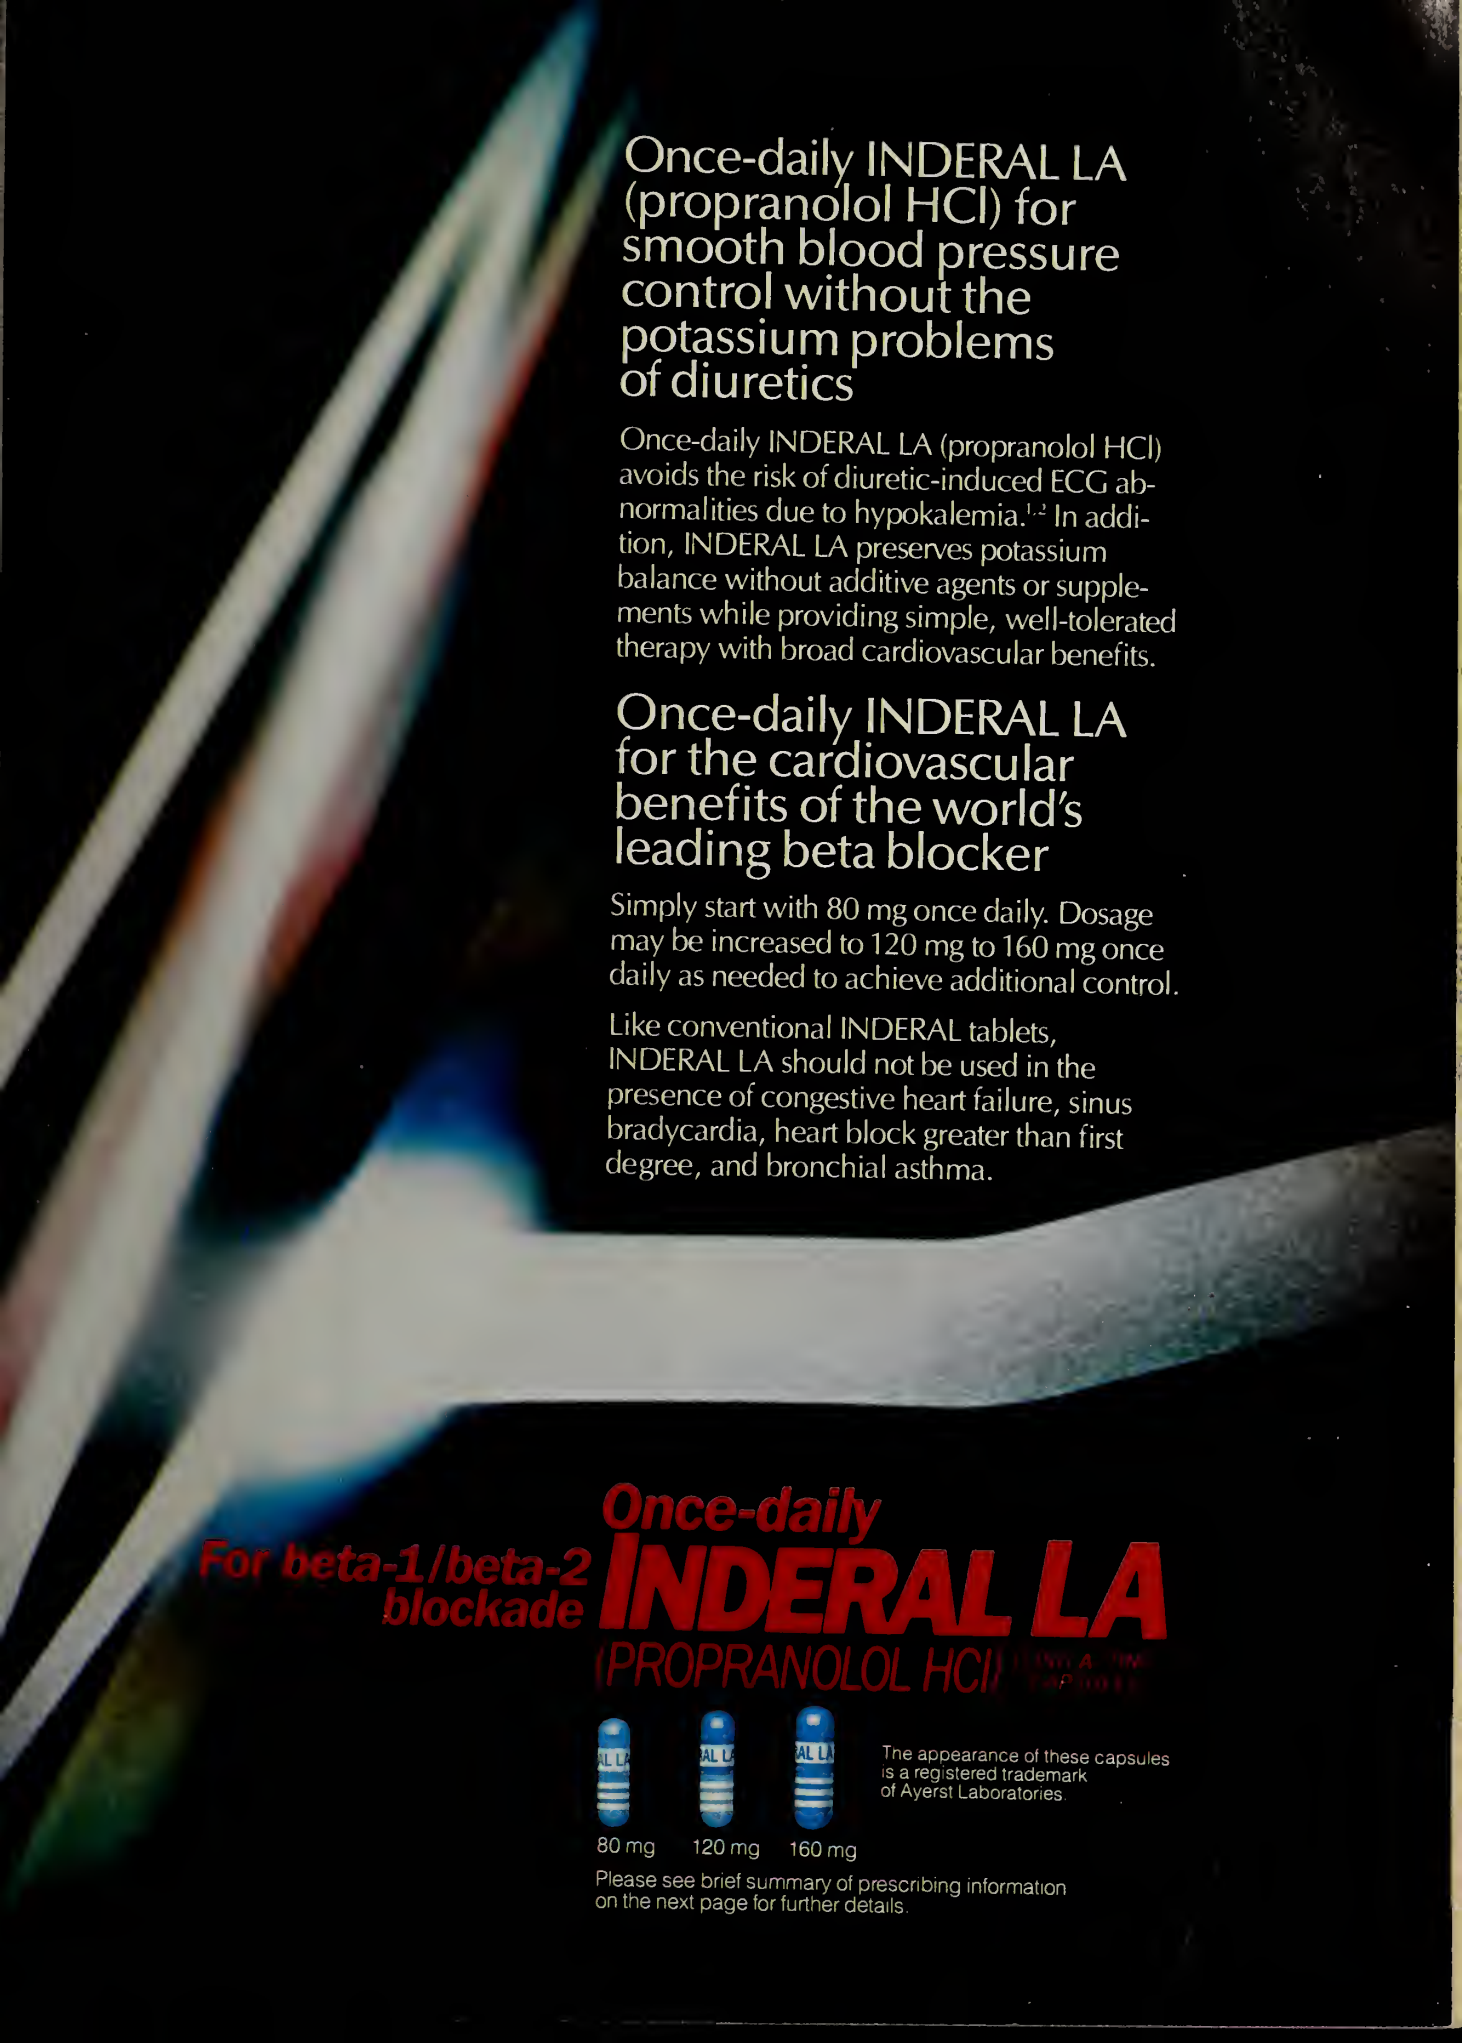
Right from the start in hypertension...



Once-daily INDERAL LA (propranolol HCl) for smooth blood pressure control without the potassium problems of diuretics

Once-daily INDERAL LA (propranolol HCl) avoids the risk of diuretic-induced ECG abnormalities due to hypokalemia.[1,2] In addition, INDERAL LA preserves potassium balance without additive agents or supplements while providing simple, well-tolerated therapy with broad cardiovascular benefits.

Once-daily INDERAL LA for the cardiovascular benefits of the world's leading beta blocker

Simply start with 80 mg once daily. Dosage may be increased to 120 mg to 160 mg once daily as needed to achieve additional control.

Like conventional INDERAL tablets, INDERAL LA should not be used in the presence of congestive heart failure, sinus bradycardia, heart block greater than first degree, and bronchial asthma.

For beta-1/beta-2 blockade

Once-daily INDERAL LA

(PROPRANOLOL HCl)

80 mg 120 mg 160 mg

The appearance of these capsules is a registered trademark of Ayerst Laboratories.

Please see brief summary of prescribing information on the next page for further details.

"When it comes to cardiovascular medicine, I like to know exactly what my patients are swallowing."

INDERAL® Tablets

BRAND OF PROPRANOLOL HCl

10 mg 20 mg 40 mg 60 mg 80 mg 90 mg*

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

INDERAL® (propranolol hydrochloride) Tablets

CONTRAINDICATIONS

INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma, 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely; or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA: Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS: Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS

General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL (propranolol hydrochloride) may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia, congestive heart failure; intensification of AV block; hypotension, paresthesia of hands; thrombocytopenic purpura, arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia, LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

When the pain and inflammation of arthritis flare up...

- FELDENE is an excellent choice for osteoarthritis and rheumatoid arthritis. Beginning with the first dose, FELDENE provides effective and long-lasting relief of arthritis pain and stiffness.[1]
- Convenient once-daily dosage provides round-the-clock relief of symptoms[2]—encouraging compliance and enhancing productivity at home and on the job.[3]

Start one-a-day

Feldene® (PIROXICAM) 20 mg capsules

For full anti-arthritic action

Please see a brief summary of FELDENE (piroxicam) prescribing information on the following page.

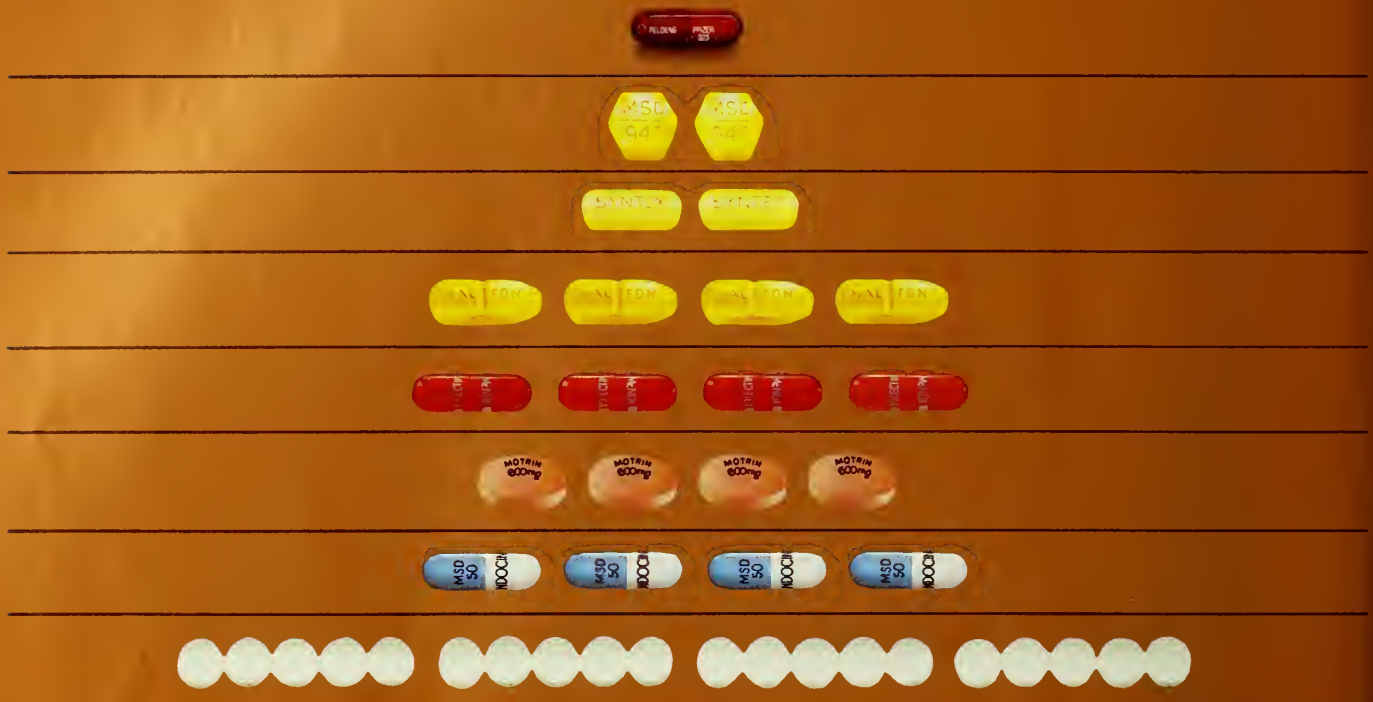
NOW ON Medi-Cal

Start one-a-day

Feldene® (PIROXICAM) 20 mg capsules

For full anti-arthritic action

Prescribe one 20mg capsule daily for convenience and compliance



Source: PDR, 1985; Manufacturers' Prescribing Information

Indicates maximum dosage for osteoarthritis and rheumatoid arthritis for the antiarthritic agents included. Consult manufacturers' prescribing information.

Brief Summary

FELDENE® (piroxicam) Capsules

CONTRAINDICATIONS: FELDENE (piroxicam) should not be used in patients who have previously exhibited hypersensitivity to it, or in individuals with the syndrome comprised of bronchospasm, nasal polyps and angioedema precipitated by aspirin or other nonsteroidal anti-inflammatory drugs.

WARNINGS: Peptic ulceration, perforation and G.I. bleeding—sometimes severe, and, in some instances fatal—have been reported with patients receiving FELDENE. If FELDENE must be given to patients with a history of upper gastrointestinal tract disease, the patient should be under close supervision (see ADVERSE REACTIONS).

PRECAUTIONS: As with other anti-inflammatory agents, long-term administration to animals results in renal papillary necrosis and related pathology in rats, mice and dogs.

Acute renal failure and hyperkalemia as well as reversible elevations of BUN and serum creatinine have been reported with FELDENE. In addition to reversible changes in renal function, interstitial nephritis, glomerulitis, papillary necrosis and the nephrotic syndrome have been reported with FELDENE.

Although other nonsteroidal anti-inflammatory drugs do not have the same direct effect on platelets that aspirin does, all drugs inhibiting prostaglandin biosynthesis do interfere with platelet function to some degree.

Because of reports of adverse eye findings with nonsteroidal anti-inflammatory agents, it is recommended that patients who develop visual complaints during treatment with FELDENE have ophthalmic evaluation.

As with other nonsteroidal anti-inflammatory drugs, borderline elevations of one or more liver tests may occur in up to 15% of patients. A patient with symptoms and/or signs suggesting liver dysfunction, or in whom abnormal liver tests have occurred, should be evaluated for evidence of the development of more severe hepatic reaction while on therapy with FELDENE.

Severe hepatic reactions, including jaundice and cases of fatal hepatitis, have been reported with FELDENE. Although such reactions are rare, if abnormal liver tests persist or worsen, if clinical signs and symptoms consistent with liver disease develop, or if systemic manifestations occur (e.g., eosinophilia, rash, etc.), FELDENE should be discontinued. (See also ADVERSE REACTIONS.)

Although at the recommended dose of 20 mg/day of FELDENE increased fecal blood loss due to gastrointestinal irritation did not occur, in about 4% of the patients treated with FELDENE alone or concomitantly with aspirin, reductions in hemoglobin and hematocrit values were observed.

Peripheral edema has been observed in approximately 2% of the patients treated with FELDENE. Therefore, FELDENE should be used with caution in patients with heart failure, hypertension or other conditions predisposing to fluid retention.

A combination of dermatological and/or allergic signs and symptoms suggestive of serum sickness have occasionally occurred in conjunction with the use of FELDENE. These include arthralgias, pruritus, fever, fatigue, and rash including vesiculo bullous reactions and exfoliative dermatitis.

DRUG INTERACTIONS: Interactions with coumarin-type anticoagulants have been reported with FELDENE since marketing. Therefore, physicians should closely monitor patients for a change in dosage requirements when administering FELDENE to patients on coumarin-type anticoagulants and other highly protein-bound drugs.

Plasma levels of piroxicam are depressed to approximately 80% of their normal values when FELDENE is administered in conjunction with aspirin (3900 mg/day), but concomitant administration of antacids has no effect on piroxicam plasma levels.

Nonsteroidal anti-inflammatory agents, including FELDENE, have been reported to increase steady state plasma lithium levels. It is recommended that plasma lithium levels be monitored when initiating, adjusting and discontinuing FELDENE.

Carcinogenesis, Chronic Animal Toxicity and Impairment of Fertility: Subacute and chronic toxicity studies have been carried out in rats, mice, dogs, and monkeys.

The pathology most often seen was that characteristically associated with the animal toxicology of anti-inflammatory agents: renal papillary necrosis (see PRECAUTIONS) and gastrointestinal lesions.

In classical studies in laboratory animals, piroxicam did not show any teratogenic potential.

Reproductive studies revealed no impairment of fertility in animals.

Pregnancy and Nursing Mothers: Like other drugs which inhibit the synthesis and release of prostaglandins, piroxicam administration continued late into pregnancy increased the incidence of dystocia and delayed parturition in animals. Gastrointestinal tract toxicity was increased in pregnant females in the last trimester of pregnancy compared to non-pregnant females or females in earlier trimesters of pregnancy.

FELDENE is not recommended for use in nursing mothers or in pregnant women because of the animal findings and since safety for such use has not been established in humans.

Use in Children: Dosage recommendations and indications for use in children have not been established.

ADVERSE REACTIONS: Gastrointestinal symptoms are the most prominent side effects, occurring in approximately 20% of the patients, which in most instances did not interfere with the course of therapy. Of the patients experiencing gastrointestinal side effects, approximately 5% discontinued therapy with an overall incidence of peptic ulceration of about 1%.

Adverse reactions are listed below by body system for all patients in clinical trials with FELDENE at doses of 20 mg/day.

Incidence Greater Than 1%: The following adverse reactions occurred more frequently than 1 in 100.

Gastrointestinal: stomatitis, anorexia, epigastric distress*, nausea*, constipation, abdominal discomfort, flatulence, diarrhea, abdominal pain, indigestion.

Hematological: decreases in hemoglobin* and hematocrit* (see PRECAUTIONS), anemia, leucopenia, eosinophilia.

Dermatologic: pruritus, rash.

Central Nervous System: dizziness, somnolence, vertigo.

Urogenital: BUN and creatinine elevations (see PRECAUTIONS).

Body as a Whole: headache, malaise.

Special Senses: tinnitus.

Cardiovascular/Respiratory: edema (see PRECAUTIONS).

* Reactions occurring in 3% to 9% of patients treated with FELDENE (piroxicam).

Reactions occurring in 1% to 3% of patients are unmarked.

Incidence Less Than 1% (Causal Relationship Probable): The following adverse reactions occurred less frequently than 1 in 100. The probability exists that there is a causal relationship between FELDENE and these reactions.

Gastrointestinal: liver function abnormalities, jaundice, hepatitis (see PRECAUTIONS), vomiting, hematemesis, melena, gastrointestinal bleeding, perforation and ulceration (see WARNINGS), dry mouth.

Hematological: thrombocytopenia, petechial rash, ecchymosis, bone marrow depression including aplastic anemia, epistaxis.

Dermatologic: sweating, erythema, bruising, desquamation, exfoliative dermatitis, erythema multiforme, toxic epidermal necrolysis, Stevens-Johnson syndrome, vesiculo bullous reactions, photoallergic skin reactions.

Central Nervous System: depression, insomnia, nervousness.

Urogenital: hematuria, proteinuria, interstitial nephritis, renal failure, hyperkalemia, glomerulitis, papillary necrosis, nephrotic syndrome (see PRECAUTIONS).

Body as a Whole: pain (colic), fever, flu-like syndrome (see PRECAUTIONS).

Special Senses: swollen eyes, blurred vision, eye irritations.

Cardiovascular/Respiratory: hypertension, worsening of congestive heart failure (see PRECAUTIONS), exacerbation of angina.

Metabolic: hypoglycemia, hyperglycemia, weight increase, weight decrease.

Hypersensitivity: anaphylaxis, bronchospasm, urticaria/angioedema, vasculitis, "serum sickness", sis (see PRECAUTIONS).

Incidence Less Than 1% (Causal Relationship Unknown): Other adverse reactions were reported with a frequency of less than 1 in 100, but a causal relationship between FELDENE and the reaction could not be determined.

Gastrointestinal: pancreatitis.

Dermatologic: onycholysis, loss of hair.

Central Nervous System: akathisia, hallucinations, mood alterations, dream abnormalities, mental confusion, paresthesias.

Urogenital System: dysuria.

Body as a Whole: weakness.

Cardiovascular/Respiratory: palpitations, dyspnea.

Hypersensitivity: positive ANA.

OVERDOSAGE: In the event treatment for overdosage is required, the long plasma half-life of piroxicam should be considered. The absence of experience with acute overdosage precludes characterization of sequelae and recommendations of specific antidotal efficacy at this time. It is reasonable to assume that the standard measures of gastric evacuation and general supportive therapy would apply. In addition to supportive measures, the use of activated charcoal may effectively reduce the absorption and reabsorption of piroxicam. Experiments in man have demonstrated that the use of multiple-dose treatments with activated charcoal could reduce the half-life of piroxicam elimination from 27 hours (without charcoal) to 11 hours and reduce the systemic bioavailability of piroxicam by as much as 37% when activated charcoal is given as late as 6 hours after administration of piroxicam.

ADMINISTRATION AND DOSAGE: Rheumatoid Arthritis, Osteoarthritis: It is recommended that FELDENE therapy be initiated and maintained at a single daily dose of 20 mg. If desired, the daily dose may be divided.

Dosage recommendations and indications for use in children have not been established.

More detailed professional information available on request.

Advertisements—The journal is published the first week of the month. Advertising copy must be received no later than the first of the month preceding issue. Advertising rates will be sent on request. Acceptance of advertising is contingent upon approval by the Advertising Committee. *The journal reserves the right to reject any advertisement.*

SUBSCRIPTION INFORMATION

The subscription price per year is $20 in the United States and Canada (US funds); $30 in all other countries. Single copies are $4.50 (which includes postage and handling). Address all subscription communications to THE WESTERN JOURNAL OF MEDICINE Circulation, 44 Gough Street, San Francisco, CA 94103-1233 • Tel: (415) 863-5522.

Allow six weeks for subscriptions to begin. Past issues must be bought individually. So long as reserve stocks are available, missing issue requests from subscribers are honored for up to six months after the issue date. Thereafter, the single copy rate of $4.50 is applicable for each issue available.

Change of Address—Requests for change of address should give both the old and new address. Allow six weeks for changeover.

SUBMITTING MANUSCRIPTS

"Information for Authors"—A complete guide to manuscript submission and journal style is available on request and also appears in January and July.

Author Responsibility—Authors are responsible for all statements, conclusions and methods of presenting subjects. Articles are accepted on condition that they are contributed solely to this journal.

Manuscripts—Ordinarily manuscripts should not exceed 3,000 words (less than 15 typed double-spaced pages). The *original* manuscript and two copies should be submitted, typed double-spaced throughout. If photographic illustrations are desired, three sets of clear, unmounted black and white glossy prints should be supplied. For line drawings, original artwork or glossy prints are acceptable. Tables should be typed on separate sheets of paper.

Clinical Investigation—Papers that authors wish considered for the Clinical Investigation section should be so designated in the transmittal letter.

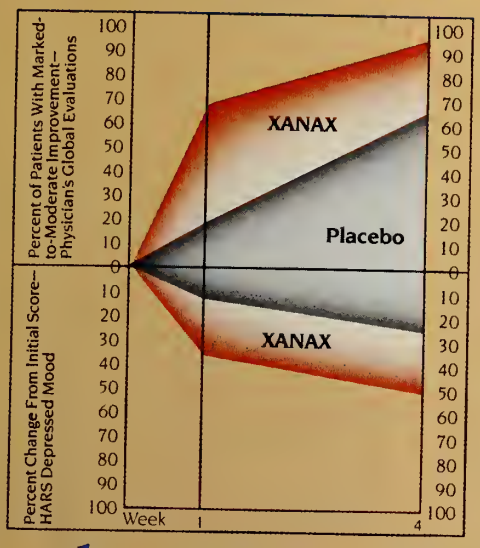
In 7 of 10
anxious
geriatrics...
Anxiety and
depressive
symptoms
go hand
in hand.

Xanax rapidly relieves anxiety with depressive symptoms.



In a recent clinical study[1] of 83 geriatric patients with clinical anxiety, 73% were diagnosed as having symptoms of depressed mood.

XANAX is well suited for therapy because it demonstrates greater efficacy than placebo in reducing the Hamilton Anxiety Rating Scale Total Score and individual items including depressed mood (see Figure).

With clinical advantages for geriatric patients.

- **Rapidly relieves** the symptoms of anxiety
- **Rapidly relieves** associated depressed mood
- **Well tolerated**—mild, transient drowsiness, the most commonly reported side effect the first week of therapy, shows a marked decrease thereafter and is not significantly different from that of placebo
- **Does not cause** cardiotoxicity
- **Specific geriatric dosage**—0.25 mg, two or three times daily

1 Cohn JB. Double-blind safety and efficacy comparison of alprazolam and placebo in the treatment of anxiety in geriatric patients. *Curr Ther Res* 1984;35(1):100-112.

Xanax® 0.25 mg Tablets
alprazolam Ⓒ IV

Upjohn THE UPJOHN COMPANY
Kalamazoo, Michigan 49001 USA

Please see next page for brief summary of prescribing information.

XANAX® Tablets
(alprazolam) ℞

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: The dosage of XANAX Tablets should be reduced or withdrawn gradually, since withdrawal seizures have been reported upon abrupt withdrawal. If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation. (See Drug Interaction section.) Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage. (See Dosage and Administration.) Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central nervous system: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting, and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other side effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analysis are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. Withdrawal seizures have occurred upon rapid decrease or abrupt discontinuation of therapy. In all patients, dosage should be gradually tapered under close supervision. Patients with a history of seizures or epilepsy should not be abruptly withdrawn from XANAX. Addiction-prone individuals should be under careful surveillance. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

DOSAGE AND ADMINISTRATION
The usual starting dose is 0.25 to 0.5 mg, t.i.d. Maximum total daily dose is 4 mg. In the elderly or debilitated, the usual starting dose is 0.25 mg, two or three times daily. Reduce dosage gradually when terminating therapy, by no more than one milligram every three days.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION

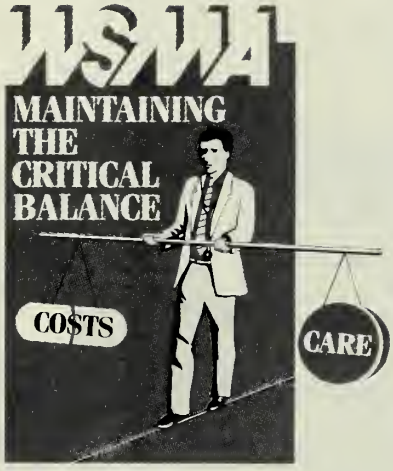
THUNDERBIRD MOTOR INN
JANTZEN BEACH, PORTLAND

Scientific Programs

Surgery, Psychiatry, Emergency Medicine, Allergy, Internal Medicine, Ophthalmology, Family Practice



ANNUAL MEETING
SEPTEMBER 19-22, 1985

Annual Meeting Speakers Varied, Provocative

An innovative no-fault approach to tort reform will be presented by Jeffrey O'Connell, professor of law at the University of Virginia. O'Connell specializes in accident and insurance law. He has authored numerous books including a 1979 work, "The Lawsuit Lottery: Only the Lawyers Win." O'Connell will speak to the House of Delegates on Thursday morning, 11:00 a.m.

Harry E. Morgan, Jr, Chairman of the Health Care Purchasers Association of Puget Sound, will also address the House. He will discuss "A Business Prospectus on the Cost of Health Care."

Thursday afternoon Susan M. Schmidt, counsel to the special AMA Task Force on Professional Liability which has produced a series of reports on the issue, will join O'Connell and Morgan on a special reference committee panel. The panel will further review the liability issue and invite physician comment.

Dr Roy M. Schwarz, AMA vice president of medical education and science policy, will address meeting attendees on Friday morning on the future direction of medical education and major science issues facing American medicine in the future.

Meeting Focuses on Change and Challenges

Maintaining the critical balance between costs and care will be an important theme of the 1985 WSMA Annual Meeting. In addition to House of Delegates sessions which will shape future WSMA action on issues, including professional liability, the event-packed four-day meeting will feature a strong social-economic program and comprehensive scientific program.

"When the Ayerst rep told me it costs about 45¢ a day, I said you can stop right there."

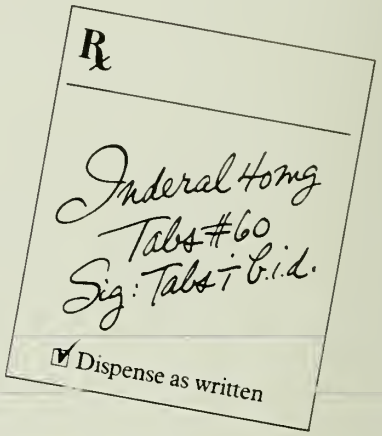
Most doctors are pleasantly surprised to learn that the average cost of daily therapy with the world's most widely used beta blocker is so little, not much more than the cost of a daily newspaper.

When it's INDERAL (propranolol hydrochloride) tablets you want for your hypertension patients, remember to specify Dispense As Written (DAW) or Do Not Substitute on your prescriptions. That way, you can always be assured they'll get INDERAL®. Please see next page for brief summary of prescribing information.

INDERAL®
(PROPRANOLOL HCl)
Small price to pay.

"When the Ayerst rep told me it costs about 45¢ a day, I said you can stop right there."

INDERAL® TABLETS
(PROPRANOLOL HCl)



BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)

INDERAL® (propranolol hydrochloride) Tablets

CONTRAINDICATIONS

INDERAL is contraindicated in 1) cardiogenic shock, 2) sinus bradycardia and greater than first degree block, 3) bronchial asthma, 4) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL.

WARNINGS

CARDIAC FAILURE. Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, if necessary they can be used with close follow-up in patients with a history of failure who are well compensated and are receiving digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta blockers can, in some cases, lead to cardiac failure. Therefore, at the first sign or symptom of heart failure, the patient should be digitalized and/or treated with diuretics, and the response observed closely, or INDERAL should be discontinued (gradually, if possible).

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following abrupt discontinuance of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced over at least a few weeks and the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease who are given propranolol for other indications.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

MAJOR SURGERY. The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

INDERAL, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in starting and maintaining the heartbeat has also been reported with beta blockers.

DIABETES AND HYPOGLYCEMIA. Beta-adrenergic blockade may prevent the appearance of certain premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia in labile insulin-dependent diabetes. In these patients, it may be more difficult to adjust the dosage of insulin.

THYROTOXICOSIS. Beta blockade may mask certain clinical signs of hyperthyroidism. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

PRECAUTIONS

General: Propranolol should be used with caution in patients with impaired hepatic or renal function. INDERAL is not indicated for the treatment of hypertensive emergencies.

Beta-adrenoreceptor blockade can cause reduction of intraocular pressure. Patients should be told that INDERAL (propranolol hydrochloride) may interfere with the glaucoma screening test. Withdrawal may lead to a return of increased intraocular pressure.

Clinical Laboratory Tests: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DRUG INTERACTIONS: Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine-blocking action may produce an excessive reduction of resting sympathetic nervous activity which may result in hypotension, marked bradycardia, vertigo, syncopal attacks, or orthostatic hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In 18-month studies in both rats and mice, employing doses up to 150 mg/kg/day, there was no evidence of significant drug-induced toxicity. There were no drug-related tumorigenic effects at any of the dosage levels. Reproductive studies in animals did not show any impairment of fertility that was attributable to the drug.

Pregnancy: Pregnancy Category C. INDERAL has been shown to be embryotoxic in animal studies at doses about 10 times greater than the maximum recommended human dose.

There are no adequate and well-controlled studies in pregnant women. INDERAL should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: INDERAL is excreted in human milk. Caution should be exercised when INDERAL is administered to a nursing woman.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Most adverse effects have been mild and transient and have rarely required the withdrawal of therapy.

Cardiovascular: bradycardia, congestive heart failure; intensification of AV block; hypotension, paresthesia of hands, thrombocytopenic purpura, arterial insufficiency, usually of the Raynaud type.

Central Nervous System: Lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue, reversible mental depression progressing to catatonia; visual disturbances; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis.

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Respiratory: bronchospasm.

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Auto-Immune: In extremely rare instances, systemic lupus erythematosus has been reported.

Miscellaneous: alopecia. LE-like reactions, psoriasiform rashes, dry eyes, male impotence, and Peyronie's disease have been reported rarely. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been associated with propranolol.

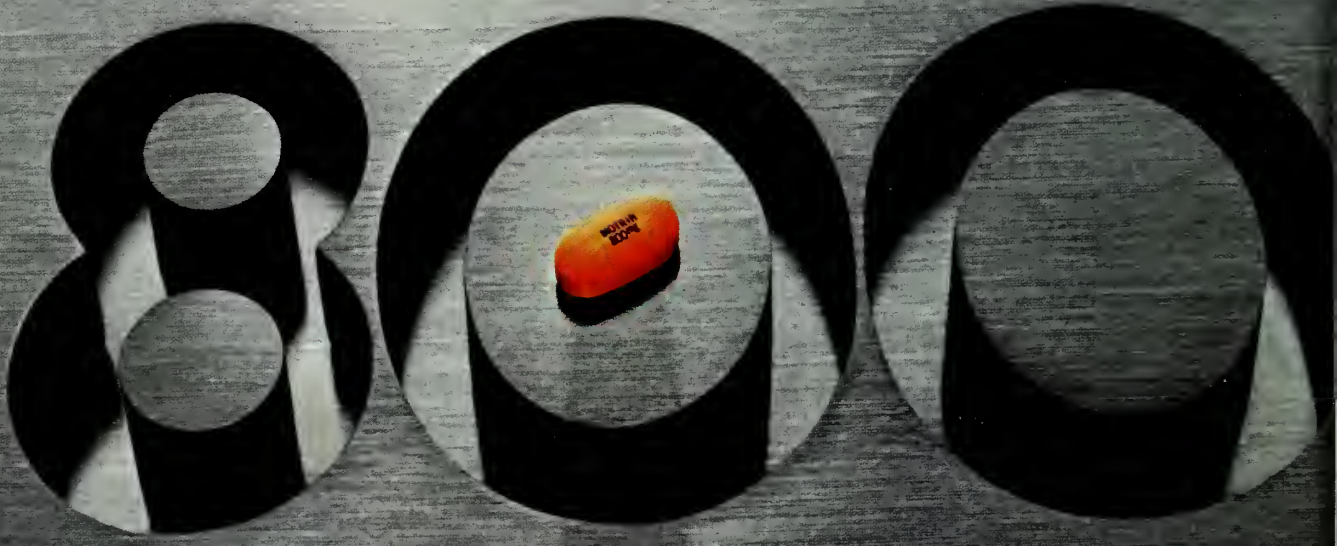
New Motrin® 800 mg TABLETS

ibuprofen



a stronger reason to prescribe Motrin Tablets

© 1985 The Upjohn Company

New Motrin® 800 TABLETS mg
ibuprofen

Extra-Strength Motrin Tablets— a convenient way to tap the full potential of Motrin:

The newest strength of *Motrin* Tablets

makes treatment easier for arthritis patients who need the doses that provide higher levels of anti-inflammatory activity as well as potent analgesia...just 1 tablet t.i.d. provides 2400 mg/day.

expands the dosage convenience of MOTRIN Tablets—makes it even easier to adjust the dosage of MOTRIN to each patient's needs...the new dosage range of up to 3200 mg/day can be achieved on a q.i.d. regimen. Gastroscopic studies at varying doses show an increased tendency toward gastric irritation at higher doses. However, at comparable doses, gastric irritation is about half that seen with aspirin.

provides economy...patients should pay less for MOTRIN Tablets than comparable dosages of Clinoril, Feldene, or Naprosyn.

provides, above all, the experience-proven efficacy and safety profile of *Motrin.* MOTRIN continues to be America's most often prescribed nonsteroidal anti-inflammatory agent.

Please turn the page for a brief summary of prescribing information.

Upjohn

The Upjohn Company, Kalamazoo, Michigan 49001

Motrin® Tablets
(ibuprofen)
Indications and Usage: Treatment of signs and symptoms of rheumatoid arthritis and osteoarthritis. Relief of mild to moderate pain and primary dysmenorrhea. Safety and efficacy in children are not established.
Contraindications: Anaphylactoid reactions have occurred in individuals hypersensitive to MOTRIN or with the syndrome of nasal polyps, angioedema and bronchospastic reactivity to aspirin or other nonsteroidal anti-inflammatory agents.
Warnings: Peptic ulceration and GI bleeding, sometimes severe, have been reported. Ulceration, perforation and bleeding may end fatally. An association has not been established. Use MOTRIN under close supervision in patients with a history of upper gastrointestinal tract disease, after consulting ADVERSE REACTIONS. In patients with active peptic ulcer and active rheumatoid arthritis, try nonulcerogenic drugs, such as gold. If MOTRIN is used, observe the patient closely for signs of ulcer perforation or GI bleeding.
Chronic studies in rats and monkeys have shown mild renal toxicity with papillary edema and necrosis. Renal papillary necrosis has rarely been shown in humans treated with MOTRIN.
Precautions: Blurred and/or diminished vision, scotomata, and/or changes in color vision have been reported. If these develop, discontinue MOTRIN and the patient should have an ophthalmologic examination, including central visual fields and color vision testing.
Fluid retention and edema have been associated with MOTRIN; use with caution in patients with a history of cardiac decompensation or hypertension. In patients with renal impairment, reduced dosage may be necessary. Prospective studies of MOTRIN safety in patients with chronic renal failure have not been done.
MOTRIN can inhibit **platelet aggregation** and prolong bleeding time. Use with caution in persons with intrinsic coagulation defects and on anticoagulant therapy.
Patients should report signs or symptoms of **gastrointestinal ulceration** or bleeding, blurred vision, skin rash, weight gain, or edema. Patients on prolonged **corticosteroid therapy** should have therapy tapered slowly when MOTRIN is added.
The antipyretic, anti-inflammatory activity of MOTRIN may mask inflammation and fever.
As with other nonsteroidal anti-inflammatory drugs, borderline elevations of liver tests may occur in up to 15% of patients. These abnormalities may progress, may remain essentially unchanged, or may be transient with continued therapy. Meaningful elevations of SGPT or SGDT (AST) occurred in controlled clinical trials in less than 1% of patients. Severe hepatic reactions, including jaundice and cases of fatal hepatitis, have been reported with ibuprofen as with other nonsteroidal anti-inflammatory drugs. If liver disease develops or if systemic manifestations occur (eg, eosinophilia, rash, etc.), MOTRIN should be discontinued.
In cross-study comparisons with 1200 mg to 3200 mg daily for several weeks, a slight dose-response decrease in hemoglobin/hematocrit was noted. The total decrease in hemoglobin usually does not exceed 1 gram.
Drug interactions—*Aspirin:* used concomitantly may decrease MOTRIN blood levels.
Coumarin: bleeding has been reported in patients taking MOTRIN and coumarin.
Pregnancy and nursing mothers: MOTRIN should not be taken during pregnancy or by nursing mothers.
Adverse Reactions: The most frequent type of adverse reaction occurring with MOTRIN is gastrointestinal, of which one or more occurred in 4% to 16% of the patients. Reported side effects were higher at 3200 than at 2400 mg/day or less.
Incidence Greater Than 1% (but less than 3%)—Probable Causal Relationship
Gastrointestinal: Nausea,* epigastric pain,* heartburn,* diarrhea, abdominal distress, nausea and vomiting, indigestion, constipation, abdominal cramps or pain, fullness of GI tract (bloating and flatulence); **Central Nervous System:** Dizziness,* headache, nervousness; **Dermatologic:** Rash* (including maculopapular type), pruritus; **Special Senses:** Tinnitus; **Metabolic/Endocrine:** Decreased appetite; **Cardiovascular:** Edema, fluid retention (generally responds promptly to drug discontinuation; see PRECAUTIONS).
Incidence Less Than 1%—Probable Causal Relationship**
Gastrointestinal: Gastric or duodenal ulcer with bleeding and/or perforation, gastrointestinal hemorrhage, melena, gastritis, hepatitis, jaundice, abnormal liver function tests; **Central Nervous System:** Depression, insomnia, confusion, emotional lability, somnolence, aseptic meningitis with fever and coma; **Dermatologic:** Vesiculobullous eruptions, urticaria, erythema multiforme, Stevens-Johnson syndrome, alopecia; **Special Senses:** Hearing loss, amblyopia (blurred and/or diminished vision, scotomata, and/or changes in color vision) (see PRECAUTIONS); **Hematologic:** Neutropenia, agranulocytosis, aplastic anemia, hemolytic anemia (sometimes Coombs positive), thrombocytopenia with or without purpura, eosinophilia, decreases in hemoglobin and hematocrit (see PRECAUTIONS); **Cardiovascular:** Congestive heart failure in patients with marginal cardiac function, elevated blood pressure, palpitations; **Allergic:** Syndrome of abdominal pain, fever, chills, nausea and vomiting, anaphylaxis; bronchospasm (see CONTRAINDICATIONS); **Renal:** Acute renal failure in patients with pre-existing significantly impaired renal function, decreased creatinine clearance, polyuria, azotemia, cystitis, hematuria; **Miscellaneous:** Dry eyes and mouth, gingival ulcer, rhinitis.
Incidence Less Than 1%—Causal Relationship Unknown**
Gastrointestinal: Pancreatitis; **Central Nervous System:** Paresthesias, hallucinations, dream abnormalities, pseudotumor cerebri; **Dermatologic:** Toxic epidermal necrolysis, photoallergic skin reactions; **Special Senses:** Conjunctivitis, diplopia, optic neuritis, cataracts; **Hematologic:** Bleeding episodes (eg, epistaxis, menorrhagia); **Metabolic/Endocrine:** Gynecomastia, hypoglycemic reaction, acidosis; **Cardiovascular:** Arrhythmias (sinus tachycardia, sinus bradycardia); **Allergic:** Serum sickness, lupus erythematosus syndrome, Henoch-Schonlein vasculitis, angioedema; **Renal:** Renal papillary necrosis.
Overdosage: In cases of acute overdosage, the stomach should be emptied. The drug is acidic and excreted in the urine so alkaline diuresis may be beneficial.
Dosage and Administration: Do not exceed 3200 mg/day.
Rheumatoid arthritis and osteoarthritis: Suggested dosage is 1200 to 3200 mg per day (400, 600 or 800 mg t.i.d. or q.i.d.). The smallest effective dosage should be used. Mild to moderate pain: 400 mg every 4 to 6 hours as necessary.
How Supplied:

MOTRIN Tablets, 400 mg (orange)	MOTRIN Tablets, 600 mg (peach)	MOTRIN Tablets, 800 mg (apricot)
Bottles of 500	Bottles of 500	Bottles of 100
Unit-dose package of 100	Unit-dose package of 100	Bottles of 500
Unit of Use bottles of 100	Unit of Use bottles of 100	

Caution: Federal law prohibits dispensing without prescription. *For additional product information, see your Upjohn representative or consult the package insert.*
*Reactions occurring in 3% to 9% of patients treated with MOTRIN. (Those reactions occurring in less than 3% of the patients are unmarked.)
**Reactions are classified under *"Probable Causal Relationship (PCR)"* if there has been one positive rechallenge or if three or more cases occur which might be causally related. Reactions are classified under *"Causal Relationship Unknown"* if seven or more events have been reported but the criteria for PCR have not been met.

A PRESCRIPTION FOR PHYSICIANS

Bothered by:

* Too much paperwork?
* The huge burden of office overhead?
* Malpractice insurance costs?
* Not enough time for the family?
* No time to keep current with technology and new methods?
* No time or money for professional development?

Join the Air Force Medical Team, we'll provide the following:

* Competent and dedicated professional staff.
* Time for patients and to keep professionally current.
* Financial security, a generous retirement for those who qualify.

* If qualified, unlimited professional development.
* Medical facilities all round the world.
* 30 days of vacation with pay each year.
* Complete medical and dental care.
* Low cost life insurance.

Want to find out more? Contact you nearest Air Force recruiter for information at no obligation.

DOCTORS IN EAST WASHINGTON–OREGON–NEVADA, MONTANA, IDAHO, UTAH, OR WEST WYOMING CALL

CAPTAIN STEVE BENTLEY (801) 524–4008 COLLECT

AIR FORCE

A great way of life.

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

★ **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: The bioavailability of the hydrochlorothiazide component of 'Dyazide' is about 50% of the bioavailability of the single entity. Theoretically, a patient transferred from the single entities of Dyrenium (triamterene, SK&F CO.) and hydrochlorothiazide may show an increase in blood pressure or fluid retention. Similarly, it is also possible that the lesser hydrochlorothiazide bioavailability could lead to increased serum potassium levels. However, extensive clinical experience with 'Dyazide' suggests that these conditions have not been commonly observed in clinical practice. Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances; postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

Supplied: 'Dyazide' is supplied as a red and white capsule, in bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

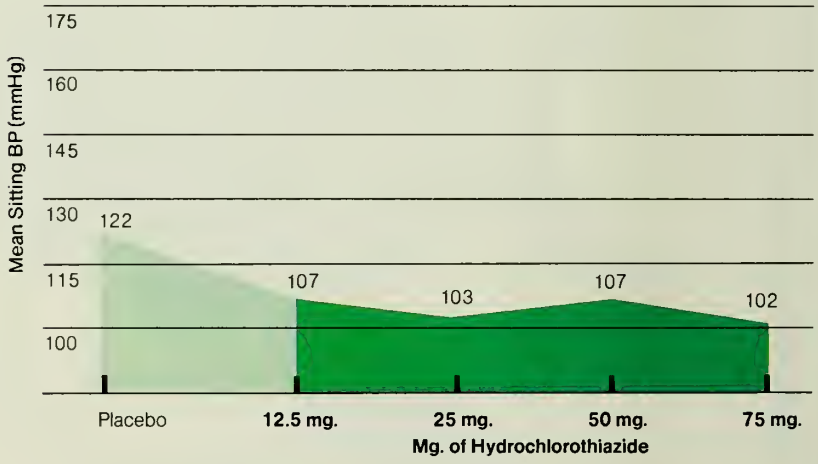
The unique red and white Dyazide® capsule: Your assurance of SK&F quality.

The Benefits of Less

Low doses of hydrochlorothiazide can provide most of the antihypertensive effect of larger doses.[1]

Increasing dosage above 25 mg. daily or improving bioavailability will not lead to increased antihypertensive efficacy in the majority of patients, but can result in a higher incidence of hypokalemia, hyperuricemia and hyperglycemia.[2]

HYDROCHLOROTHIAZIDE: FLAT DOSE-RESPONSE CURVE[3]



For the benefits of low dose diuretic therapy* with the added benefit of potassium-sparing triamterene

The Effects of Magnetic Resonance Imaging on Intravenous Infusion Devices

MARY B. ENGLER, MS, *and* MARGUERITE M. ENGLER, MS, *Bethesda, Maryland*

We evaluated the effects of magnetic resonance imaging on the accuracy of three types of intravenous infusion pump devices, IVAC 530, IMED 927 and IMED 960/965. The devices were exposed to a 2,800-gauss static magnetic field at a pulsed radio frequency of 11.9 MHz operating at a maximum power of 1,200 W. Each device was tested at low, medium and fast flow rates in a controlled environment and during magnetic resonance imaging. Intravenous therapy could be carried out normally during magnetic resonance diagnostic imaging only with the IVAC 530 infusion device.

(Engler MB, Engler MM: The effects of magnetic resonance imaging on intravenous infusion devices [Clinical Investigation]. West J Med 1985 Sep; 143:329-332)

The clinical importance of magnetic resonance (MR) imaging in patient diagnosis is becoming widely recognized. Mechanical functions can be affected significantly by exposure to MR imaging, however, creating special safety considerations for patients using any instrumentation during such studies. The safety of intravenous infusion devices is always of significant concern, but the possible effect of MR imaging on these devices requires particular consideration.

Precise intravenous fluid or medication delivery can be critical to a patient. The potential for fluid overload, dehydration, medication bolus or nontherapeutic medication delivery can be life-threatening, especially to a critically ill patient. In this study, we investigated the possibility that magnetic field interaction with intravenous devices might result in inaccurate fluid delivery to a patient. This was undertaken by examining the effects of the magnetic field of MR imaging on the function of three types of intravenous devices—the IMED 927 volumetric pump, the IMED 960/965 volumetric pump and the IVAC 530 nonvolumetric peristaltic pump.

Review of Literature

MR imaging is a valuable diagnostic technique. The concept of MR spectroscopy was developed in 1946 by Bloch and by Purcell and co-workers,[1,2] and has been used for years in analytical chemistry and biology. Damadian used the MR method in 1971 for detecting cancer in human tissue.[3] The first MR imaging study was done in the early 1970s by Lauterbur, who obtained cross-sectional pictures of water-filled capillary tubes.[4] In 1977 the first human body MR images were made[5] and further perfected with improved images of the extremities and head.[6,7]

The images displayed by MR imaging are similar to x-ray computed tomographic (CT) scans, but MR imaging is superior to computed tomography in some regards. CT scans require exposing patients to potentially harmful ionizing irradiation, whereas MR imaging uses pulsed and static magnetic fields at levels not known to cause any harm to the human body. MR imaging also gives good discrimination of the body's soft tissues, whereas CT shows only density.

Magnetic resonance imaging has shown promise for evaluating myocardial function and for detecting atherosclerosis, cancer, brain and demyelinating diseases and kidney, liver and pancreatic diseases.[8-11] Future physiologic applications are also predicted for MR imaging to provide essential biochemical and metabolic information.[12-14]

As with any new procedure, there are potential problems with MR imaging. It was originally postulated that MR imaging units could induce electrical currents, resulting in local tissue heating with metal surgical clips and prostheses. No significant heating of clips or prostheses has been reported as yet.[15] Patients with cardiac pacemakers should not have MR imaging. A pacemaker might be reprogrammed or switched into a fixed-rate mode by the magnetic field in a manner similar to pacemaker magnets used clinically to change modes. Pacemaker interference and a torque movement sufficient to cause rotation have been documented with exposure to magnetic resonance.[16] This torque movement resembles the dial of a compass moving in the direction of the magnetic

MR = magnetic resonance

field. Possible rotation of the pacemaker within the surgically implanted area is cause for concern, as is the potential for inducing arrhythmia by conduction generated in the pacemaker cardiac lead. These pacemaker problems appear to be associated with ferromagnetic metal components.

Other research has indicated that MR imaging may generate enough longitudinal forces and torques to risk dislodgement of certain vascular clips, resulting in hemorrhage or injury to surrounding tissues.*[17] Clearly, all of the reported effects of MR imaging are of paramount clinical importance; at present, no reports appear in the literature on the effects of MR imaging on intravenous infusion devices.

Methods

Three types of intravenous devices that regulate intravenous infusion were tested. The total study sample included six IMED 927 volumetric pumps, three IMED 960/965 volumetric pumps and four IVAC 530 nonvolumetric peristaltic pumps. As a control, the intravenous devices were first tested in the ambient earth's magnetic field.† Then each device was subjected to the same tests in varying magnetic field strengths near the MR system's magnet.

Each intravenous pump device was evaluated at slow, medium and fast rates in a controlled environment and within the fringe magnetic field of the MR system. The devices were exposed to a 2,800-G static magnetic field with a pulsed radio frequency of 11.9 MHz operating at a maximum power of 1,200 W. The magnetic field at the center of the MR imaging magnet opening was measured at 1,500 G. The MR imaging magnetic fringe field strengths at each of the intravenous device locations were measured with a Digital Gaussmeter Model 811 (F. W. Bell, Inc).

The study was conducted using 0.9% sodium chloride solution infused through manufacturer's infusion sets specific for each type of pump. The solution was allowed to flow through the tubing, connected to plastic syringes for the slow and medium rates and graduated cylinders for the fast rate. Single-use plastic syringe (12 ml, 60 ml) fluid collections serve as a method of measuring delivered volume equivalent to using graduated cylinders. All air was expelled from the tubing and syringes to ensure accuracy before testing. The effluent from each device at the three rates was collected and measured at one-hour intervals during the control and MR imaging trials. All devices operated on line current rather than batteries during both control and magnetic exposure.

The intravenous devices in the system's magnetic fringe field were placed at two locations away from the center of the MR unit opening (Figures 1 and 2). Close positioning of the intravenous devices was measured at 0.9 m (3 ft), 30 degrees away from the center of the magnet opening. Distant positioning was designated at 4 m (13 ft), 60 degrees away from the center of the magnet opening.

The magnetic fringe field strength of the MR imager for the four IVAC 530 devices at the close position was measured at 415 to 500 G, depending on the vertical location of the device on the intravenous pole. This position for the pole was chosen because it represented the closest practical location during MR imaging. The three IMED 960/965 devices had an MR imaging exposure field of 440 to 525 G at the close location, which was then decreased to the distant position of 9 to 10 G. The six IMED 927 devices were exposed to a close MR imaging field of 450 to 700 G, which was decreased to 9 to 12 G at the distant location.

Uniform gauss values in the MR imaging fringe field were difficult to maintain due to the logistics of device placement. Biomedical engineering performance checks of the devices were conducted before and after the study to certify electrical circuitry performance and conformance with the manufacturers' specifications. Statistical significance of differences was assessed by paired Student's *t* test. The *t* test was used to determine the effect of the MR imaging exposure on device accuracy. The effects of confounding variables—that is, device type and infusion speed—were determined by two-factor analysis of variance. A two-sided *P* value of less than .05 was considered statistically significant.

Results

All of the IMED 927 and IMED 960/965 intravenous devices tested were within the manufacturer's specifications ±2% accuracy before MR imaging exposure. However, the IVAC 530 devices were ±3.3%, which exceeds the manufacturer's prescribed accuracy for a controlled environment. Because this difference in calibration for the IVAC 530s was known before measurement in the magnetic field, it was taken into account when reporting deviations in accuracy due to magnetic effects.

The IMED 927 devices *failed* to deliver fluid in the 450 to

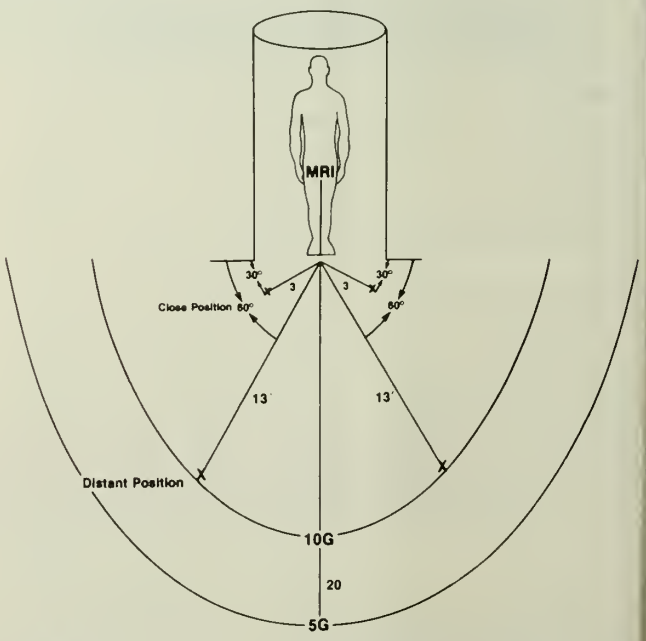

Figure 1.—The magnetic strength field plot of magnetic resonance imaging (MRI) and intravenous device positions. G = gauss

*It should also be emphasized that safety precautions must be undertaken with any ferromagnetic object including intravenous devices in the MR imaging vicinity. Ferromagnetic objects can be converted into dangerous projectiles within the MR imaging field, posing considerable risk to a patient, personnel, or both.

†Gauss (G) is a unit of magnetic field strength. The earth's magnetic field is approximately 0.5 G.

700 G MR imaging close fringe field; thus, no statistical analysis was completed on these data. The IMED 960/965 devices were significantly affected by 440 to 525 G exposure ($t = -2.695$, degrees of freedom *[df]* 8, $P = .02$). Although the mean error was only 1.5% (less than the error allowed by the manufacturer's specifications), the range across the three samples tested was from 1% to 4%. The IVAC 530 devices operated normally at the calibration level within the 415 to 500 G close magnetic field with no statistically significant difference detected between the flow rates in the control and the magnetic environment ($t = 0.165$, df 11, no significance).

In an effort to identify a location in the MR imaging fringe field that would allow for proper operation of both types of IMEDs, the magnetic field exposure was decreased until proper operation was observed at 9 to 12 G for the IMED 927 and 9 to 10 G for the IMED 960/965. This gauss level was measured at the distant position, as previously described. There was no significant difference between flow rates for the IMED 960/965 in the control and decreased MR imaging field exposure ($t = -0.255$, df 8, no significance). The MR imaging exposure for the IMED 927 was decreased to 9 G for three devices, 10 G for two devices and 12 G for one device. A statistically significant difference in flow rate persisted in the 10 to 12 G range ($t = -3.306$, df 8, $P < .01$); the mean error rate was 2.3% (above the manufacturer's ±2% specification for accuracy). The data from the three IMED 927 devices at 9 G also reflected a persistence in statistically significant flow rates ($t = -8.044$, df 8, $P < .005$), although the mean error rate was only 1.3%. It is interesting to note that the error rates for the IMED 927 decrease as the MR imaging field exposure decreases: 12 G, 2.7%; 10 G, 2.0%, and 9 G, 1.3%.

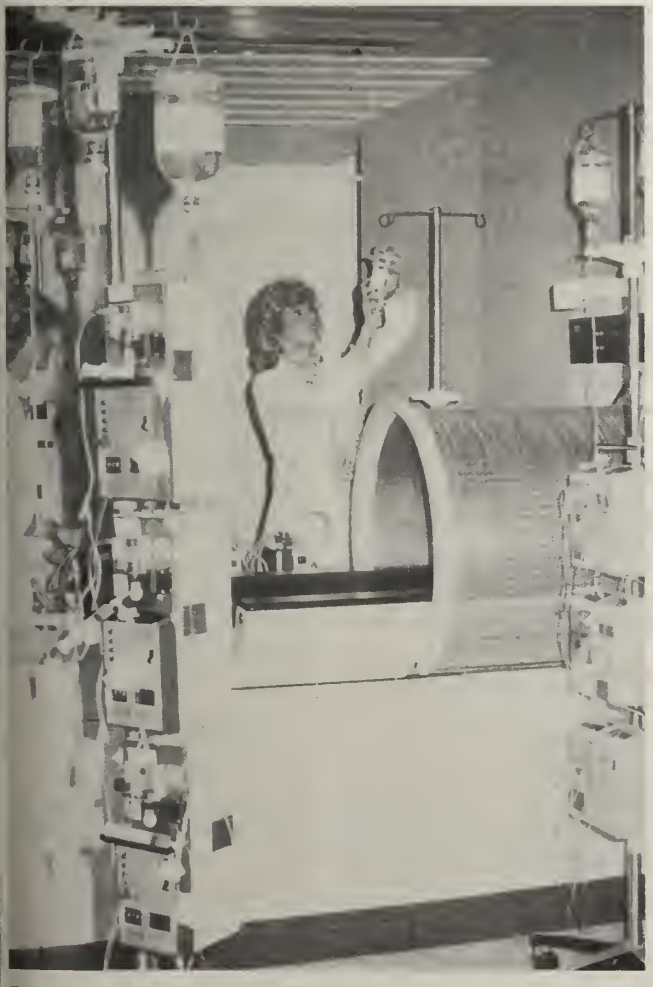

Figure 2.—Intravenous infusion pump devices within the magnetic resonance imaging area during testing. (Photo courtesy of the National Institutes of Health, Bethesda, Maryland).

Differences in the operation of the two types of IMEDs in the decreased MR imaging field were then compared using analysis of variance techniques. Three devices of each type were matched for MR imaging exposure (one device at 9 G, two devices at 10 G) only at the medium flow rate to ensure device independence. There were no statistically significant differences between the IMED 927 and 960/965 devices when the MR imaging field was decreased. There was, as expected, a statistically significant difference between the operation of the IVAC 530 and IMED 960/965 in the original MR imaging field ($t = -26.51$, df 5, $P < .0001$).

Biomedical engineering checks of all intravenous devices certified proper manufacturers' performance specifications (excluding the IVAC 530 devices calibrated at ±3.3% accuracy) and electrical circuitry following MR imaging exposure.

Discussion

The data verify that the IVAC 530 can operate normally within the MR imaging field. The IMED 960/965 can also function properly, but at a decreased MR imaging field of 9 to 10 G. The IMED 927 did not operate optimally at the decreased MR imaging field of 9 to 12 G; the mean error rate was 0.3% above the manufacturer's ±2% specifications for accuracy.

A significant difference exists between the IMED 927 in the controlled environment and the 450 to 700 G MR imaging field. The IMED 927 devices' complete *failure* to deliver fluid in this field is clinically critical. It is apparent that the IMED 927 device cannot be used for intravenous infusion regulation in close proximity to an MR imaging unit. Although the mean error for the IMED 960/965 in the 440 to 525 G MR imaging field was within the manufacturer's ±2% specification for accuracy, the range of errors was from 1% to 4%. This large rate of error could jeopardize patient safety. Furthermore, the IMED 960/965 and 927 devices at the decreased magnetic field strength showed no statistically significant difference between their accuracies, implying the monitoring of these devices at 9 to 12 G is warranted.

If the use of the IMED 960/965 at a distant location in the MR imaging field is considered, the feasibility of additional intravenous tubing attached from the patient to the IMED should be further addressed. Additional tube length appears to be necessary to limit access with the IMED 960/965 to about 10 G.

A limitation of the study is that while the measurements were made under conditions simulating clinical use, they were in fact not done under actual patient use. Possible confounding variables such as device age, frequency of device use and different viscosity of intravenous fluids were not in the scope of this study.

Clinical implications include a clinician's judgment in selecting an intravenous pump device to assure proper delivery of fluid or medication to a patient during MR imaging. The

data support the safe use of the IVAC 530 close within the MR imaging field and the IMED 960/965 at a level of 10 G. The IMED 927 and 960/965 should not be used close within the MR imaging field. Studies of the effect of MR imaging on additional types of intravenous devices, and the potential for intravenous devices to cause artifacts on MR images, should be pursued.

Medical Practice Question

EDITOR'S NOTE: *From time to time medical practice questions from organizations with a legitimate interest in the information are referred to the Scientific Board by the Quality Care Review Commission of the California Medical Association. The opinions offered are based on training, experience and literature reviewed by specialists. These opinions are, however, informational only and should not be interpreted as directives, instructions or policy statements.*

Laser Therapy for Plantar Warts

QUESTION:

Is it accepted medical practice to treat plantar warts by laser therapy?

OPINION:

In the opinion of the Scientific Advisory Panels on Dermatology and Orthopedics, laser therapy can be considered established practice in the treatment of plantar warts, but not as a routine or initial form of therapy. Its use should be reserved for lesions that have proved therapeutically unresponsive to other conservative means of treatment such as chemocautery, cryosurgery or electrosurgery. Where lesions are recurrent or very extensive, such as mosaic warts, or multiple, particularly periungual warts, laser therapy may be justified. For most patients with plantar warts, however, there is no conclusive evidence that laser therapy is more effective than less expensive modalities.

Effects of Accidental Chlorine Inhalation on Pulmonary Function

NIRMAL B. CHARAN, MD, *Boise, Idaho;* S. LAKSHMINARAYAN, MD, *Seattle;*
G. CHRISTOPHER MYERS, MD, *Palo Alto, California, and* DORSETT D. SMITH, MD, *Seattle*

In an industrial accident, 19 previously healthy workers were briefly exposed to high concentrations of chlorine gas. Pulmonary function tests were done at intervals for about two years but complete follow-up data were available in only 11 subjects. Immediately following the exposure, airway obstruction was detected in 10 of 19 patients; 700 days later this was found in only 3 of 11 patients. Two of these three patients had a history of smoking, however. The mean residual volume was 141% ± 97 (mean ± standard error of the mean) on day 1. In subsequent follow-up studies, the residual volume progressively fell in all patients, and 700 days later the mean residual volume was 90% ± 5. In 5 of the 19 subjects, all pulmonary function test results were within normal limits on day 1. Apparently in some subjects acute exposure to chlorine gas may cause immediate changes in the lung functions, but these changes gradually resolve. Because of the small number of patients in our series, however, the long-term effects of chlorine are less apparent.

(Charan NB, Lakshminarayan S, Myers GC, et al: Effects of accidental chlorine inhalation on pulmonary function [Clinical Investigation]. West J Med 1985 Sep; 143:333-336)

Chlorine is a heavy, yellowish green irritant gas with a specific gravity 2.49 times that of air. It is commonly used as a bleaching agent in the paper and textile industries and also to disinfect water and sewage. For industrial uses, it is liquefied under pressure and stored or transported in steel cylinders. When released, 1 liter of liquid chlorine produces 434 liters of chlorine gas at 25°C.[1] Lung injuries from inhalation are usually a consequence of accidental leakage from the containers and result primarily from the oxidative effect of nascent oxygen liberated by chlorine gas in the presence of water. The formation of hydrochloric acid causes further damage, although it is 20 times less severe than the oxidative effect of chlorine.[2]

The reported consequences of accidental chlorine inhalation have been conflicting with residual pulmonary abnormalities noted in some series,[3] whereas in others no significant permanent damage was found.[4,5] This report deals with an industrial accident in which 19 healthy subjects were exposed to high concentrations of chlorine. We report the immediate and long-term effects of chlorine exposure on the pulmonary function of these subjects.

Exposure Incident and Methods

The accident occurred in a pulp mill. A flexible hose connecting a railroad car filled with liquid chlorine accidentally became disconnected, resulting in the escape of a large volume of chlorine gas.

The ambient temperature at that time was about −1°C (30°F) without an appreciable wind. Because the walls of adjoining buildings were warm, the chlorine gas rose along the walls and settled as a yellow-green cloud on the roof. The actual concentration of chlorine in this cloud was not measured but was estimated to be more than 1,000 parts per million (ppm) in view of the color of the cloud. Several construction workers were on the roof of this building with no prior experience with chlorine gas and they did not have gas masks. When they saw the green cloud coming up, they tried to escape into a chlorine-free area inside the building. They were all exposed to the chlorine, however, although the duration of exposure varied in individual subjects from a few seconds to a few minutes. There were no deaths.

All 19 patients were men with a mean age of 37 years (range, 25 to 61 years); 14 were current smokers, 3 were

VC = vital capacity

exsmokers and 2 had never smoked. Pulmonary function test results before the exposure were not available for any of them. All exposed workers were admitted to hospital for 24 to 48 hours and most of them were given supplemental oxygen. Corticosteroids were not given. The initial evaluation included physical examination, chest roentgenogram and arterial blood gas determinations. Pulmonary function tests were done on all subjects within the first 24 hours. The pulmonary function tests included spirometry, static lung volumes by the nitrogen wash-out method and single-breath diffusing capacity of the lung for carbon monoxide (DLCO). The predicted normal values used were those of Higgins and Keller for spirometry,[6] Goldman and Becklake for lung volumes[7] and McGrath and Thomson for the DLCO.[8] These pulmonary function tests were repeated after 10 days in all, after 40 days in 16, after 310 days in 13 and after 700 days in 11 workers.

Results

The immediate symptoms of exposure included irritation of eyes, nose and throat, tightness in the chest and paroxysms of cough. The symptoms subsided within 24 to 48 hours in all patients. On physical examination there were no abnormalities and chest roentgenograms on admission showed transient pulmonary infiltrates in five patients that cleared in follow-up studies. Clinically unmistakable pulmonary edema did not occur in any patient.

Immediately following the exposure, 10 of 19 patients (53%) had a ratio of forced expiratory volume in one second (FEV_1) to vital capacity (VC) of less than 75%, suggesting airflow obstruction (Table 1), and, of these, 6 showed partial reversibility (improvement in FEV_1 of greater than 15%) after inhaling isoproterenol. After ten days, this ratio was less than 75% in only seven (37%) patients. The airflow obstruction, as indicated by the FEV_1-VC ratio and a mean forced expiratory flow during 75% to 25% of vital capacity (FEF_{25-75}) below 60% of predicted, continued to abate in some subjects, and two years later only 3 of 11 subjects studied had an FEV_1-VC ratio of less than 75%. One of these three persons had never smoked.

Of the 19 patients, 13 (68%) had a residual volume of greater than 120% of predicted immediately following the exposure (Figure 1 and Table 1). However, the residual volume progressively fell in subsequent studies, and two years later 6 of 11 patients (55%) had residual volumes of less than 80% of predicted. The absolute fall in residual volume in these six patients was 0.58 ± 0.19 liters (mean ± standard deviation [SD]) between day 10 and day 700. None of the 11 subjects studied on day 700 had a residual volume of more than 120% predicted. The mean residual volumes on day 1, day 7, day 40, day 310 and day 700 were $141\% \pm 9$ (mean ± standard error of the mean [SEM]), $121\% \pm 6$, $106\% \pm 6$, $97\% \pm 7$ and $90\% \pm 5$, respectively. There was a significant difference between mean residual volume (% predicted) on day 1 and day 700 ($P < .001$) and also between day 40 and day 700 ($P < .05$). Similar reductions, although of lesser degree, were noted in functional residual capacity. No significant changes were noted in total lung capacity, functional residual capacity and vital capacity (Figures 1 and 2).

Although not all 19 subjects completed follow-up pulmonary function testing at two years, a telephone contact with these patients found that none of the subjects had died and, for the most part, they were asymptomatic.

Single-breath nitrogen plateau (phase III) and closing volume (phase IV) were also studied. However, the number

of patients with abnormal results was no greater than the number of patients with an abnormal FEV_1-VC ratio or abnormal FEF_{25-75}. Arterial blood gas determinations were made in all the subjects, and on day 1, two were found to have mild hypoxemia that improved to normal by day 10. Single-breath DLCO studies did not show any consistent trends or abnormalities.

Discussion

The earliest accurate account of chlorine inhalation associated with lung injury was reported by Lehmann in 1887,[9] who described hemorrhagic pulmonary edema in animals following experimental exposure to chlorine gas at a concentration of 1 ppm. However, it was not until the second year of World War I when chlorine gas was introduced as a weapon of war that its toxic potential received any particular attention. The pulmonary effects of chlorine on about 2,000 victims of gas attacks were reported by Berghoff.[10] He found that in 50% of the soldiers either bronchitis or emphysema developed and that the subjective symptoms far exceeded clinical findings.

The long-term pulmonary sequelae of accidental exposure to chlorine in humans have been described in few reports. However, the degree and the type of abnormality vary from report to report. Kowitz and co-workers[3] studied 11 subjects serially for three years and reported decreased lung volumes, presumably due to patchy atelectasis and nodular scarring. They postulated that humans who inhale a high concentration of chlorine gas suffer acute alveolar damage that heals with subsequent pulmonary fibrosis in six months to two years. However, none of their patients had a lung biopsy. Weil and associates[4] studied 12 persons serially for seven years following accidental chlorine exposure. They concluded that significant permanent lung damage does not result from acute exposure to chlorine gas. Review of their data, however, showed that in 1964 none of the four subjects studied had residual volumes of less than 80% of predicted, whereas in 1968 five of seven had a residual volume below 80% of predicted. Chester and colleagues[11] studied the effects of long-term exposure to low concentrations of chlorine (average concentration, 1 ppm) in chlorine gas plant workers. Of the 139 workers, 55 had additional accidental exposures severe enough to require oxygen therapy. They found only three workers with abnormalities, and they had evidence of significant airway obstruction.

Winternitz and co-workers[12] exposed dogs to massive concentrations of chlorine gas to study the sequential morphologic changes. They found that animals dying within 24 hours of exposure had tracheitis, bronchitis with peribronchial inflammation and focal necrosis of lungs. The animals dying two to five days after the exposure had evidence of pulmonary infection, mainly pneumonia and bronchitis, whereas the animals dying 15 to 193 days after the exposure showed evidence of bronchitis and bronchiolitis. The small airway disease was seen only in the acute phase and most of the animals recovered completely from this, suggesting that the involvement of the small airways was mild and did not result in the severe bronchiolitis obliterans usually seen with massive and prolonged exposure.

The airflow obstruction that was noted in our subjects on day 1 could be attributed to acute inflammatory changes in the airways. On days 310 and 700, 5 of 13 (38%) and 3 of 11 (27%) patients continued to show spirometric evidence of airflow obstruction. Of the three patients who continued to have airflow limitation, two were heavy smokers, and in these two patients airflow limitation could be related to their smoking habits. Only one person was a nonsmoker and chlorine could have been the causative agent in him. However, because of the small number of patients with this abnormality in this series, no conclusion regarding the long-term effects of chlorine inhalation on airflow obstruction can be drawn from this study.

An elevation of the residual volume immediately following chlorine exposure could be explained by air trapping as a result of bronchospasm and mucosal inflammation of the airways. Therefore, the residual volume would be expected to fall rapidly to the baseline values with the resolution of mucosal inflammation and edema. This would explain the decrease in the residual volume in the first ten days. A further fall in the residual volume from day 10 to day 700 also appears to be related to continuation of the healing process. Although on day 700, the mean residual volume in our study was within normal limits, 6 of the 11 subjects had a residual volume below 80% of that predicted. The cause for a decreased residual volume in these subjects is not apparent. Mild peribronchiolar fibrosis in the healing phase would make the bronchioles stiffer and hence more resistant to closure during exhalation. Leith and Mead[13] have shown that the residual volume in healthy, young persons (younger than 35 years) is determined by the limitation of chest wall, and in older persons (older than 35 years) it is determined by airway collapse. Stiffening of the airways by peribronchial fibrosis would keep the airway patent at lower lung volumes, thus allowing a low residual volume. Another possibility is that the pulmonary injury heals with fibrosis, which would increase elastic recoil of the lung. The increased elastic recoil will also favor a low residual volume by its tethering effect on small airways, tending to keep them open at low lung volumes while permitting a nearly normal expansion at total lung capacity. Without a lung biopsy specimen in these subjects, the mechanisms described above remain speculative. The clinical implications of this degree of reduction in the residual volume seen in our patients are not apparent and it is unlikely that it would cause any major respiratory symptoms.

Currently, chlorine is used extensively in industry, and the National Institute of Occupational Safety and Health has estimated that 15,000 workers in the United States are at risk for possible exposure to chlorine.[14] Pulmonary injuries due to inhaling chlorine are usually a consequence of industrial accidents. Therefore, the concentration and the duration of exposure vary in the individual subjects. Furthermore, chlorine is a strong respiratory irritant, which tends to limit the length of exposure. This could explain why some studies show no residual pulmonary function abnormalities. However, a longer duration of exposure to higher concentrations of chlorine gas may result in long-term pulmonary function abnormalities.

These opinions are, however, informational only and should not be interpreted as directives, instructions or policy statements.*

Stereotactic Heavy-Ion Irradiation of Arteriovenous Malformations

QUESTION:

Is it accepted medical practice to treat arteriovenous malformations by the radiosurgical method of stereotactic heavy-ion irradiation?

OPINION:

In the opinion of the Scientific Advisory Panels on Neurosurgery and Radiology, stereotactic heavy-ion bragg peak radiosurgery is considered a promising but still investigational treatment for deep, inoperable arteriovenous malformations (AVMs) of the brain. The procedure has been advocated for those select patients in whom the AVM cannot be safely surgically excised, cannot be treated with any form of embolization or in which, following embolization carried out at one or multiple stages, there remains some residual AVM that cannot be controlled. To date, only two centers in the United States have the specially trained personnel and sophisticated equipment necessary to apply this treatment method.

Though recent reports indicate that this technique can be applied safely, effectively and at low risk to patients, the total number of patients treated thus far has been small. Follow-up in two of the three studies reported has been for a relatively short period of time, two years or less. In one series, only 20% of patients had complete obliteration of the AVM; in the other, although most patients had a decrease in the size of the AVM after a period of months, none had complete obliteration.

Long-term study findings are not yet available to address questions such as recanalization, delayed hemorrhage, the delayed response in the reduction and obliteration of the AVM and the associated risks of large dose radiation. Therefore, as neither the technique nor its outcome has been conclusively defined and because continued basic research and clinical investigation is advocated by those working in this field, stereotactic heavy-ion bragg peak radiosurgery for arteriovenous malformation should be classified as an investigational procedure.

Toxic Shock Syndrome in Utah—1976 to 1983

JAY A. JACOBSON, MD; CRAIG R. NICHOLS, MPA, *and* EVELYN M. KASWORM, MT, *Salt Lake City*

The sustained high incidence of staphylococcal toxic shock syndrome (TSS) in Utah provided an opportunity to examine changes in the epidemiology of this disease during a period of greater media attention to the syndrome and increased scientific understanding of its etiology and pathogenesis. An apparent peak in the statewide incidence of TSS in 1980 appears in part attributable to self-reporting of outpatient cases. The incidence of the syndrome in patients having a nasal operation appears equal to or greater than the incidence in menstrual-age women. The case-fatality ratio and recurrence rate of TSS have declined since widespread recognition of the syndrome, possibly related to earlier diagnosis and initiation of antistaphylococcal therapy. Identifying milder cases has also contributed to a lower mortality.

(Jacobson JA, Nichols CR, Kasworm EM: Toxic shock syndrome in Utah—1976 to 1983. West J Med 1985 Sep; 143:337-341)

Although Todd and co-workers first labeled toxic shock syndrome (TSS) in 1978,[1] most of the medical profession and the public first learned of it from the lay press in 1980. TSS was subsequently characterized as a new, dangerous, often lethal illness strongly associated with menstruation, tampon use and possibly the use of one brand of tampon in particular.

Older reports of "staphylococcal" scarlet fever,[2] Todd's investigation of toxic shock syndrome in children[1] and case-control studies conducted in 1980[3,4] all implicated *Staphylococcus aureus* in the pathogenesis of TSS. Strains of *S aureus* recovered from patients with TSS have been associated with the production of exotoxins: specifically, epidermal toxin,[5] staphylococcal enterotoxin F[6] and staphylococcal pyrogenic exotoxin C.[7] The latter two may represent the same material in different laboratories. The pathogenic role of these toxins in humans is not yet well established, and tests for identifying their presence are not widely available. Thus, the diagnosis of TSS continues to be a clinical one and requires meeting criteria established in a case definition.

While there remains some debate as to whether staphylococcal toxic shock syndrome is a "new" disease, there is little doubt that it has been more commonly recognized in recent years. The incidence of the syndrome reported nationally has peaked and fallen within the past five years,[8] and this has been attributed to changes in recognition and reporting, in the availability of certain catamenial products and possibly in the way in which tampons are used. Accompanying the change in reported incidence of this syndrome has been an appreciation of a wider variation in clinical expression and the realization that the syndrome can and often does occur independent of menstruation.[9]

The incidence of reported cases of TSS in Utah and several other states has been inexplicably high and sustained. Utah was one of only four states in 1980 with an incidence above 1 per 100,000. The others were Minnesota, Wisconsin and Oregon.[10] As of June 1983, three states—Utah, Wisconsin and Minnesota—accounted for 28% of TSS cases reported in the United States.[8]

The first 135 cases of TSS reported in Utah had onsets of illness from 1976 to 1983. These cases provided an opportunity to examine secular trends and changes in the epidemiology, clinical presentation, management and outcome of this syndrome during the period when knowledge about and awareness of TSS were increasing rapidly.

Patients and Methods

The toxic shock syndrome has been a reportable disease in Utah since March 1980, when Utah physicians were alerted about this syndrome by an article in the *Communicable Disease Newsletter* published by the Utah Department of Health. Cases suggestive of TSS have been identified through reporting by physicians, hospitals, bacteriology laboratories, patients, patients' family members and local health departments. Reports have also been solicited by active monthly telephone surveillance of infection control practitioners in all 38 hospitals in the state. The state health department has sought details of the illness from the patients' physicians, the

medical records and in most instances the patients. A case is considered confirmed if it meets the modified case definition used by the Centers for Disease Control.[10] For the purpose of this study, additional case-finding efforts included a search of the consultation records of a hospital-based infectious disease division and a telephone survey of all of the otorhinolaryngologists practicing in the state. The state of Utah records demographic and clinical information about cases of the toxic shock syndrome on a form designed for that purpose. These records and the medical records of patients admitted to LDS Hospital were the primary sources of data for this report. The LDS Hospital is a 530-bed community and tertiary care hospital academically affiliated with the University of Utah Medical School. There are two full-time infectious disease physicians on the hospital staff. An infectious disease fellow and internal medicine trainees are regularly assigned to the clinical consultation service. Frequent formal and informal teaching sessions about TSS have been conducted at this hospital since 1980.

Cases were defined as menstrual if their symptoms of TSS began during or within two days of menses. Cases were considered postpartum if they occurred after delivery but more than two days before menses resumed. Postsurgical cases were those in which there was an obvious temporal and anatomic relation to an operative procedure independent of menstruation. All other cases were categorized as spontaneous. A recurrent case of TSS was defined by the presence of desquamation and at least two major criteria of the case definition.[3]

Population data were derived from the 1980 census and official estimates of the population for the years 1976 to 1983. Data on live births were derived from the Utah Bureau of Vital Statistics.

The relative risk for a menstrual-age woman was calculated by dividing the incidence of TSS in this population by the incidence in men and nonmenstrual-age women. The percentage of risk attributable to being a menstrual-age woman was calculated by subtracting the incidence in the population exclusive of this group from the incidence in this group and dividing by the incidence in menstrual-age women. The relative risk of menstruation was calculated in a similar fashion using the assumption that about 30% of menstrual-age women would be menstruating or would be within two days of menses on the day a case occurred. Thus, the relative risk of menstruation for menstrual-age women was the incidence in menstruating women divided by the incidence in nonmenstruating women of menstrual age. The percent attributable risk was the difference in those rates divided by the incidence in menstruating women.

Results

The first reported case of TSS in Utah occurred in 1976. Between 1976 and July 1983, 134 more cases had occurred and been reported. The incidence peaked in 1980, a year of intense publicity about the association between the syndrome and menstruation and tampon use (Figure 1). Subsequently, the overall incidence has been about 1.7 per 100,000 persons per year. There has been no consistent seasonal trend. Most of the sharp increase in incidence in 1980 could be accounted for by menstrual cases occurring at a rate of 12.7 per 100,000 menstrual-age women and averaging 5.3 since then. The incidence of nonmenstrual cases has been relatively constant since 1977, averaging about 0.13 per 100,000 per year. All but one case that occurred before 1979 were menstrual, while in 1980 to 1983, three to five cases per year (9% to 33% of the total) have been unrelated to menstruation (Figure 2). Of 120 menstrual cases, 119 have occurred in women using tampons. The relative risk for women of menstrual age (15 to 44 years) has declined from a high but indeterminate value to a range of about 20 to 30 since 1980. The attributable risk percent for this group has ranged from 95% to 100%. In years when it could be determined, the relative risk of menstruation in women of menstrual age was sharply higher in 1980 at 168, and the average for the period since has been 58. The attributable risk percent for menstruation, however, in menstruating women has consistently been between 92% and 100%. Obviously, most cases of TSS occur in women, but when menstrual and postpartum cases are excluded, the female-male ratio is still 4.5 to 1. Cases were not identified in men before 1981. All cases of TSS in Utah have occurred in whites. The black population, however, is only 0.63% of Utah's population and numbered 9,225 in the 1980 census.

The average age of the women in menstrual cases of TSS is 24.3 years. The age-specific attack rates by five-year age

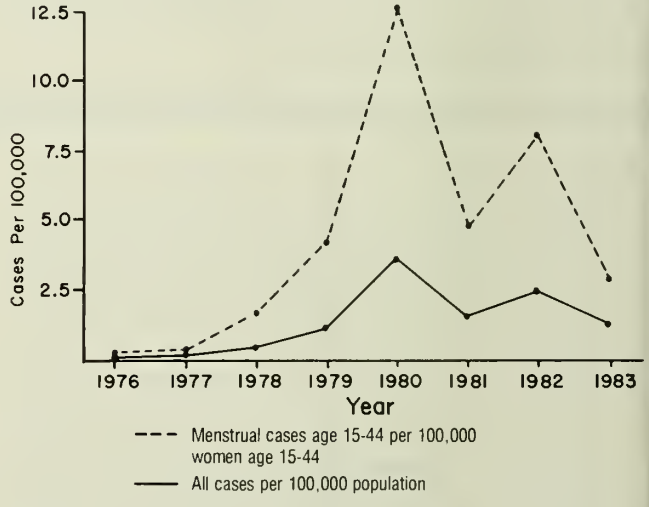

Figure 1.—Incidence of toxic shock syndrome in Utah, 1976 to 1983.

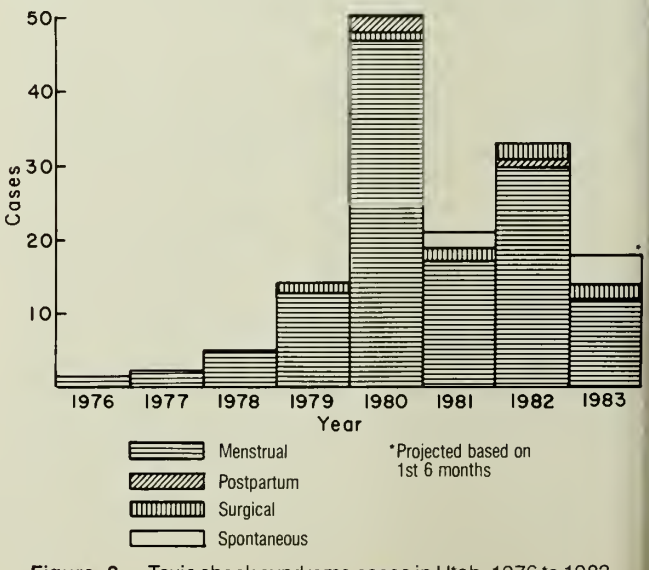

Figure 2.—Toxic shock syndrome cases in Utah, 1976 to 1983.

groups show similar rates in women aged 15 to 30 years, 4.5 per 100,000. The attack rate for women aged 30 years and older drops progressively to 0.7 per 100,000 in women aged 45 to 49 years. The average age of patients with menstrual TSS and the pattern of age-specific attack rates for this form of the syndrome have not changed substantially over the past eight years.

Postsurgical cases have occurred following nasal operations (four cases), abdominal hysterectomy (one case) and umbilical herniorrhaphy (one case). The average age of all postsurgical cases was 28.3 years, and for those having a nasal procedure it was 28.5 years. Appropriate denominators were not available with which to calculate incidence and age- and procedure-specific attack rates for all of these cases. However, our survey of ear, nose and throat physicians indicated that for 1981 and 1982, the estimated annual incidence of TSS following a nasal surgical procedure is 32 per 100,000. The average age of patients having such procedures is between 25 and 35 years, suggesting that the age-specific attack rate in this group may not be disproportionately high.[11]

Postpartum cases of TSS were first recognized in Utah in 1980. Based on live births to Utah residents, the average annual incidence for postpartum TSS would be 3.0 per 100,000. The relative risk for the postpartum state has ranged between 0 and 4.2 through 1983.

Spontaneous cases of TSS were first recognized in Utah in 1977. Since 1976, an average of 0.6 cases per year has been confirmed. These have been associated with minor staphylococcal skin infections and, in one case, staphylococcal superinfection of the vesicles of herpes zoster.[12]

At the LDS Hospital, in contrast to the state, the number of cases of TSS per 10,000 admissions, exclusive of transfers, has remained relatively stable since 1977, varying between 0.4 and 0.8, with the exception of 1980 when the incidence was 1.5. Also, in contrast to the rest of the state, the proportion of nonmenstrual cases initially admitted to LDS Hospital is quite high (Figure 3). This has been true since 1977 (4 of 11 versus 12 of 124, $P = .05$).

In the course of this study, we discovered three confirmed and four suspected cases of TSS admitted to LDS Hospital that had not been previously reported. One confirmed case had occurred in 1977, one in 1978 and one in 1982. Thus, as of July 1983, 13 of 16 (81%) cases of TSS at the LDS Hospital had been officially reported to the state.

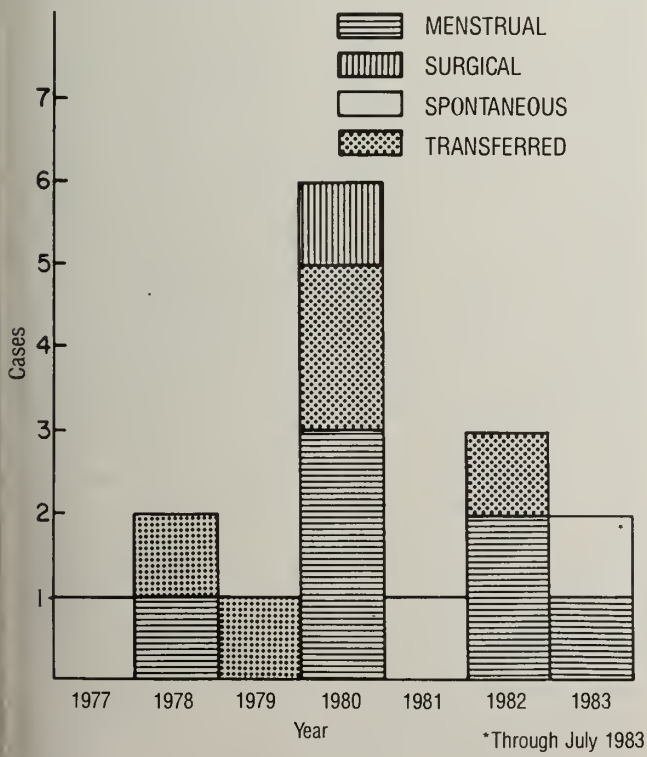

Figure 3.—Toxic shock syndrome cases at LDS Hospital, 1977 to 1983.

Clinical Presentation

The clinical presentation of the 120 menstrual cases of TSS seen in Utah since 1976 conforms closely to published descriptions.[3,4] The only two deaths, however, following menstrual cases occurred before 1980, and these were the only deaths occurring from the syndrome in Utah.

Arthralgias, not specifically mentioned in the case definition, were quite common in patients with menstrual-related TSS (64%) but were not mentioned by other patients. Involvement of the genital mucosa has been regularly reported in cases of menstrual TSS, but it occurred frequently in our nonmenstrual cases as well. Three of four women with surgical and spontaneous cases of TSS had a vaginal discharge described as thick and white.

Management

The severity, complexity and multiple-organ system involvement of TSS is apparent from the diversity of physicians involved in primary or consultative care of the patients (Table 1). Generalists and gynecologists were most likely to see the patients initially.

TABLE 1.—*Medical Specialties Involved in the Care of 16 Patients With Toxic Shock Syndrome at LDS Hospital, 1977 to 1983*

Specialty	*Number of Patients*

	Year							
	1976	*1977*	*1978*	*1979*	*1980*	*1981*	*1982*	*1983*
In-hospital cases	1	2	4	13	31	19	27	9
Total cases	1	2	5	14	50	21	33	9
(Percent)	(100)	(100)	(80)	(93)	(62)	(91)	(82)	(100)

Most reported TSS cases were admitted to hospital (Table 2). In an exceptional year, 1980, 38% were treated as outpatients or received no treatment at all. Most of these cases were self-reported.

As awareness of TSS has increased, it appears that fewer cases are referred to tertiary care hospitals for diagnosis and management. Before 1981, 6 of 52 (11.5%) of patients admitted to hospital statewide were transferred whereas since then only 1 patient of 55 (1.8%) has been.

The proportion of nontransferred cases receiving intensive care at the LDS Hospital has changed relatively little in seven years. Six of eleven patients began their hospital stay in special units. The length of stay in intensive care units has varied between one and five days. It has been declining since 1980. The duration of hospital stay has shown no consistent trend and has averaged 5.6 days.

The medical management of patients with TSS admitted to LDS Hospital has changed somewhat since the syndrome was publicized in 1980 (Table 3). The use of vasopressors, corticosteroids and blood or plasma (or both) has decreased significantly. Antibiotics were used for all cases before and after 1980, but the choice and number of drugs have apparently changed. Before 1980, all patients received antistaphylococcal antibiotics as part of empiric multidrug therapy. These included erythromycin (one), clindamycin (two), cephalosporins (two) and nafcillin sodium (one, in a patient who also received cefoxitin). Monotherapy with nafcillin was used only after 1980 and since then has been used in about half of the patients. However, 11 of 12 patients received nafcillin. The other patient was treated with a cephalosporin. Additional antibiotics were used in seven cases, but in two the sole additional agent was gentamicin sulfate, chosen because of possible synergistic antistaphylococcal activity.

Outcome

The overall case-fatality rate for TSS was 2 of 35 (5.7%) before April 1980 and 0 of 100 since. The case-fatality rate for patients admitted to hospital before April 1980 was 2 of 26 (7.7%) and 0 of 80 since ($P < .05$). Medical management of the early fatal cases included nafcillin, fluid replacement, vasopressors and removal of tampons that were used by these two menstruating women. One patient had an exploratory abdominal operation because of abdominal pains, but no abnormalities were discovered. Both patients were admitted to intensive care units and received the type of monitoring and supportive therapy used for subsequent cases admitted in these units.

Recurrence of TSS has also declined since 1980. Before then, 9 of 20 (45%) patients having menstrual TSS had a second episode within three months after the first, whereas since then only 8 of 100 (8%) patients with menstrual TSS have had a recurrence ($P < .05$). Experience at LDS Hospital suggests that this reduction in recurrence may be associated with the use of penicillinase-resistant β-lactam antibiotics. Two of seven (29%) patients with menstrual-associated TSS who received such therapy had TSS a second time compared with two of three patients who did not receive this class of drugs (P = no significance, Fisher's exact test). Antistaphylococcal β-lactam antibiotics were used for all of the nonmenstrual cases at the LDS Hospital. One of these, a woman with a staphylococcal pustule on her thigh evident during her first episode, was readmitted nine days after discharge with recurrent TSS and no apparent focus. She had received a two-day course of nafcillin, 12 grams per day, in the hospital, and then completed an eight-day course of dicloxacillin, 250 mg orally every six hours.

TABLE 3.—*Medical Therapy for Toxic Shock Syndrome at LDS Hospital, 1977 to 1983 (Patients Treated/Total Patients)*

Period	Type of Therapy				
	Vaso-pressors	Cortico-steroids	Blood and/or Plasma	Nafcillin Sodium Alone	Multiple Antibiotics
1977-1979 . . .	2/4	3/4	2/4	0/4	4/4
1980-1983 . . .	2/12	2/12	4/12	5/12	7/12

Discussion

Toxic shock syndrome was first recognized in Utah at about the same time as in other parts of the United States. The reported incidence in Utah, however, has been higher than in the nation as a whole both at the time the incidence was peaking nationally in 1980 and subsequently.[8] Better surveillance and reporting have been suggested as the reason for the higher sustained incidence in Utah. Our discovery of three unreported confirmed cases and four suspected cases at our own hospital suggests that reporting in the state is certainly not perfect, but similar case-finding efforts in other states can clarify whether our reporting is really superior. Active surveillance in Utah is most likely to identify in-hospital cases of TSS. Cases not identified as TSS and even TSS cases that do not come to the attention of infection control practitioners are less likely to be reported.

The sharp peak in the state's incidence in 1980 parallels that seen nationally. Certainly, some of the milder, outpatient, self-reported menstrual cases were recorded in that year in large part because of extensive publicity given then to TSS in the national and state media.[13] A less dramatic change in the incidence of cases admitted to hospital and a relatively constant rate of nonmenstrual cases also suggest this may be the case. On the other hand, changes in the use of tampons or the withdrawal of Rely brand tampons from the market (or both) may also have contributed to the decline in menstrual cases. The experience with menstrual TSS at LDS Hospital is interesting with respect to this possibility. The incidence of menstrual TSS actually varied relatively little between 1977 and 1983 except for 1980 when three nontransferred cases were diagnosed. Two of the patients were users of Rely tampons. Our retrospective search for TSS cases and our sustained interest in the syndrome since 1980 make it unlikely that the increase in cases detected at our hospital in 1980 was primarily due to publicity. Such a phenomenon could be due to an as-yet-unrecognized factor affecting incidence in 1980, coupled with the very frequent use of Rely tampons by menstruating women in Utah. Our previous controlled study,[14] however, while it did show frequent use of Rely tampons by control patients, showed significantly greater use in cases of TSS ($P < .005$; relative risk, 6.11). Regardless of the reason for the perturbation in the incidence of TSS in 1980, the Utah experience suggests that menstruation and probably tampon use remain important risk factors for this syndrome. Our data also suggest that the postpartum state and certain surgical procedures such as nasal procedures may be associated with

an incidence of TSS similar to that occurring in women of menstrual age.

The average age of menstrual, postpartum and postsurgical cases of TSS may simply be indicative of the average age of persons exposed, but the absence of a trend toward a higher age-specific attack rate in younger age groups is a bit surprising if antibody acquired in youth is presumed to be protective. Even more interesting is the paucity of spontaneous cases of TSS in children who often sustain skin lacerations and abrasions that are likely to be infected with *S aureus*.

The multisystem involvement characteristic of TSS was obvious in our cases but expected by virtue of a case definition that required involvement of at least three organ systems.[10] In addition to involvement of the systems specified in the definition, many of our patients with menstrual TSS complained of arthralgias, suggesting another direct or indirect target for the presumed toxin of TSS. None of these patients had arthritis, and staphylococcal joint infection was not suspected clinically. The involvement of mucous membranes in patients with TSS, particularly the genital mucosa, is emphasized by the observation that even patients without a vaginal focus of infection or menstruation did have some evidence of local reaction as manifested by an abnormal vaginal discharge.

The relatively steady incidence of nonmenstrual TSS cases at the LDS Hospital and their high proportion of total cases compared with the rest of the state suggest that a sustained high level of awareness of the various circumstances in which TSS occurs may lead to increased recognition of cases that are not "classic." If this is so, it also suggests that the actual incidence of nonmenstrual TSS is substantially higher than reported even in Utah and that these cases may be less often correctly diagnosed and reported than menstrual TSS. In a controlled study, physicians showed a bias toward diagnosing TSS in menstruating women.[15]

The high case-fatality ratio first associated with TSS undoubtedly resulted, in large part, from selective diagnosis and reporting of the most severe cases. Recognizing milder cases could be expected to reduce the ratio, as could understanding the cause of the syndrome and prescribing the proper treatment. It is interesting that the mortality for in-hospital cases in Utah is lower now than before April 1980. This may be due to earlier patient or physician recognition of the syndrome and timely admission to hospital. It seems less likely to be attributable to changes in patient management since this has changed very little over time. It does appear that recurrence of TSS has declined over time in Utah and quite possibly, as others have suggested, as the result of more rational selection of antibiotic therapy.[4] Recurrences of menstrual TSS have been explained on the basis of persistent vaginal carriage of staphylococci, cyclical bleeding and tampon use in women who are slow or unable to mount a protective immune response. Antibiotics might be expected to interrupt this pattern at least temporarily if they are successful in changing the vaginal carriage of staphylococci. Unfortunately, the effectiveness of parenteral drugs in accomplishing this has not been well documented.

While milder cases of TSS are now being recognized, this end of the spectrum is truncated because of the rigidity of the case definition. A sensitive and specific diagnostic test would clarify the range of clinical manifestations associated with infection by exotoxin-producing staphylococci. Although menstrual cases continue to predominate, the recent recognition of TSS following delivery, nasal and other operations poses a new and intriguing problem to those concerned with nosocomial infections.[9,16] The efficacy of parenteral antibiotic prophylaxis in preventing TSS has not been studied. Interestingly, it is not routinely used for most procedures after which TSS has occurred in Utah because of the low rate of bacterial infection associated with a clean surgical procedure and a normal delivery.

Advances in the Treatment of Metastatic Prostatic Cancer

JACK S. ELDER, MD, *and* ROBERT P. GIBBONS, MD, *Seattle*

Several exciting new forms of therapy for metastatic prostatic cancer have been introduced recently. Luteinizing hormone-releasing hormone (LH-RH) agonists paradoxically inhibit pituitary release of luteinizing hormone, resulting in a fall of serum testosterone to castrate levels within two to four weeks. These drugs have no cardiovascular side effects. A nonsteroidal antiandrogen, flutamide, may be as effective as orchiectomy in men with untreated metastatic disease and has the advantage of preserving potency in most men. In recent reports, combining the LH-RH agonist with an antiandrogen resulted in "total medical castration," which may substantially improve objective response rates and patient survival. Ketoconazole, an antifungal drug, also rapidly inhibits testicular and adrenal androgen synthesis and decreases plasma testosterone to castrate levels within 72 hours. In men with hormone-resistant disease, combination chemotherapy may produce an objective response rate of 50%. In men with severely painful bony metastasis, an inexpensive drug used in Paget's disease, etidronate disodium, may be palliative.

(Elder JS, Gibbons RP: Advances in the treatment of metastatic prostatic cancer. West J Med 1985 Sep; 143:342-345)

Carcinoma of the prostate is the second most common form of cancer in the older male population; nearly 23,000 men die of the disease each year.[1] At present, most patients with newly diagnosed prostatic cancer have advanced disease, with about a third having distant metastases.[2]

Background

In the early 1940s the dependence of prostate function and prostatic cancer growth on the presence of sufficient levels of circulating androgens was recognized, and Huggins and coworkers reported dramatic subjective and objective improvement in several patients with terminal metastatic prostatic cancer by doing bilateral orchiectomies.[3] In addition, it was learned that endocrine therapy often provides relief of bone pain, anorexia and obstructive symptoms, regression of osteoblastic and pulmonary metastatic lesions and reduction in hydronephrosis caused by local extension of the tumor. Since then endocrine therapy has remained the cornerstone of first-line therapy in men with metastatic disease, and Huggins was awarded the Nobel prize in 1966 for his work.

Kinetic studies in experimental tumor models have shown that prostatic cancer is composed of a heterogeneous population of androgen-dependent and -independent cells.[4] Following androgen ablation (orchiectomy), androgen-sensitive cells regress. However, the residual androgen-insensitive cell population continues to proliferate slowly, often resulting in a patient's death. Following first-line endocrine therapy such as bilateral orchiectomies, there are residual circulating adrenal androgens. However, adrenal androgen levels are quite low, and adrenal ablation apparently does not result in further disease regression.

The various methods of hormonal manipulation used in prostate cancer therapy are shown in Table 1. These include ablating the source of androgen, inhibiting luteinizing hormone-releasing hormone (LH-RH) or pituitary luteinizing hormone (LH), administering antiandrogens—compounds that compete directly with endogenously produced androgens for receptor sites in the target tissue—and inhibiting androgen synthesis.[5] Some drugs have more than one site of action.

The most reliable form of hormonal treatment is bilateral orchiectomy, which represents the standard against which other forms of management are compared, in terms of both objective and subjective responses and of side effects. The advantages of bilateral orchiectomies include the following: the operation may be done on an outpatient basis under local anesthesia; serum testosterone levels are always reduced to

castrate levels, usually within three or four days, and the side effects associated with estrogen therapy are obviated. However, some men have significant psychological trauma following castration. In such patients, leaving the epididymis, which has no hormonal function, may help alleviate patient reluctance to undergo gonadectomy; the epididymis is about the size of an atrophic testis.

Diethylstilbestrol (DES) is the least expensive (Table 2) and the most commonly used form of estrogen for managing prostatic cancer. Estrogens decrease androgen production by inhibiting LH release by the anterior pituitary (thus preventing testosterone production by the testis) and increase serum concentration of testosterone-estrogen-binding globulin, which decreases the circulating free testosterone. Side effects include gynecomastia (which may be reduced by administering low-dose radiation therapy to the nipples before initiating therapy), fluid retention, nausea and vomiting and an increased incidence of cardiovascular disease, particularly if 5 mg per day is taken. One disadvantage of DES therapy is that patients taking 1 mg a day do not always have sustained castrate testosterone levels throughout the day, although this may be alleviated by increasing the dosage to 2 to 3 mg a day in divided doses. In addition, testosterone levels do not drop as rapidly as they do following orchiectomy. Another disadvantage is that patients who experience relief of symptoms may not take the hormone on a regular basis as prescribed, simply because they feel better. Therefore, patient compliance is not as assured as it is with orchiectomy.

Following the initial evaluation of a case of metastatic prostatic cancer, indications for administering hormonal therapy are mostly subjective and include the bone pain, obstructive symptoms, anorexia, malaise or hematuria. The presence of significant anemia or hydronephrosis due to locally advanced disease also is an indication for promptly starting treatment. In asymptomatic patients, however, the decision whether to initiate hormonal therapy immediately or to wait until symptoms appear is left to the urologist. There is

no evidence that "early" hormonal therapy of asymptomatic patients results in better survival than "delayed" therapy.

Following either orchiectomy or DES therapy, 40% achieve complete or partial regression and 40% show disease stabilization.[6] The mean duration of response is about 90 weeks. Following further disease progession, as shown by worsening bone pain or new areas of metastatic disease, the mean survival is about six to ten months. Survival and objective response rates are not improved by combining orchiectomy and DES.

In the past decade, several new exciting agents have appeared that may have substantial impact on the future management of patients with metastatic disease.

LH-RH Agonists

In 1971 Schally and co-workers reported the isolation, description and synthesis of the molecular structure of the decapeptide luteinizing hormone-releasing hormone (LH-RH) (pyro-Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2).[7] Schally subsequently synthesized potent analogue agonists that possess 15 to 50 times more LH-releasing activity than the naturally occurring hormone.[8] The analogues were created by substituting a D-amino acid (alanine, *t*-butyl serine, tryptophan or leucine) for glycine in the sixth position of the decapeptide chain, removing the terminal amino acid and adding an ethylamide moiety to the proline at position 9. This results in increased affinity by the synthesized molecule

to the pituitary receptor site. Schally received the Nobel prize in 1977 for his work.

The result of administering these analogues is that there is an abrupt increase in LH release and testosterone production. However, prolonged administration has the paradoxic effect of inhibiting pituitary release of LH (and follicle-stimulating hormone), resulting in a dramatic fall in serum testosterone levels. This probably results from pituitary depletion of LH with down-regulation of the hypothalamic-pituitary axis, desensitization of the testis to LH because of reduced gonadal LH receptor sites and possibly direct gonadal steroid enzyme inhibition. Serum testosterone is reduced to castrate level (60 ng per dl) within two to four weeks. All patients have a transient rise in plasma testosterone because of the initial pituitary stimulation.

We participated in a collaborative phase I study of one analogue, leuprolide acetate, to evaluate the side effects and efficacy of this type of drug. We found that 10% to 20% of men have a "disease flare" characterized by worsening bone pain and occasionally worsening hydronephrosis, probably due to the rise in serum testosterone levels. However, drug-related cardiovascular or thromboembolic problems and gynecomastia have been rare. About 50% to 75% have vasomotor hot flashes, and most have significantly diminished libido and erectile impotence.

As previously noted, the current standard of therapy is orchiectomy or DES and, as part of the National Prostatic Cancer Project (NPCP), we are participating in a prospective randomized trial, protocol 1700, comparing standard therapy with that using another LH-RH agonist, buserelin acetate, to determine whether objective response rates and survival are better with the experimental drug (Table 3). Although LH-RH analogues are administered subcutaneously, there has been excellent patient compliance. There is no known difference in hormonal response among various LH-RH agonists. Although the drugs are still investigational, the absence of significant side effects often associated with oral estrogen therapy makes them attractive possible substitutes.

Antiandrogens

A potent antiandrogen useful in metastatic prostatic cancer therapy is flutamide, which is a nonsteroidal drug. It neither inhibits gonadotropin secretion nor suppresses plasma testosterone, but appears to prevent binding of dihydrotestosterone to the nuclear androgen receptor. It may offer an additional advantage over conventional hormonal therapy in that potency appears to be preserved in most patients and there is no known cardiovascular morbidity.[9] Mild gynecomastia develops in most patients within two to eight months. Flutamide is still investigational and is being tested at several medical centers to determine its efficacy in men with untreated prostatic cancer. At present, it is unknown whether flutamide is as effective as orchiectomy or DES.

In an effort to prevent disease flare associated with the initial use of LH-RH agonists and to eliminate the effect of circulating adrenal androgens, Labrie and associates have reported adding an antiandrogen to the regimen when starting therapy.[10] They reported that not only do patients not have disease flare, but also there is a significantly higher objective response rate—nearly 100%—compared with 60% to 85% with conventional hormonal therapy. Although this is an exciting observation, it has not been substantiated by any other investigator. Their findings are controversial because men with locally advanced disease without distant metastasis are included. However, the NPCP has recently begun a prospective double-blind randomized trial, protocol 2200, to determine whether the combined form of treatment offers any advantage over conventional therapy.

TABLE 3.—*Current Protocols of the National Prostatic Cancer Project for Patients With Prostatic Cancer With Distant Metastases (Stage D2)*

Protocol Number	*Type of Study Patient*	*Treatments*
1700	Newly diagnosed stage D2	DES/orchiectomy *v* buserelin acetate (LH-RH agonist) *v* DES/orchiectomy + methotrexate
2200	Newly diagnosed stage D2	Leuprolide acetate + flutamide *v* leuprolide + placebo (double-blind study)
1500	Stage D2, hormone failure, no pelvic irradiation	Methotrexate *v* doxorubicin + cyclophosphamide *v* cisplatin + 5-FU + cyclophosphamide
2400	Stage D2, hormone failure, failure, with or without pelvic irradiation	Estramustine phosphate sodium (Emcyt) *v* flutamide

DES = diethylstilbestrol, 5-FU = 5-fluorouracil, LH-RH = luteinizing hormone-releasing hormone

Inhibition of Androgen Synthesis

Another class of drugs that may be beneficial in the endocrine management of prostatic cancer is the imidazoles. Ketoconazole is an orally administered drug that is used in the treatment of fungal infections. At high dosages it rapidly inhibits the production of both testicular and adrenal androgens by inhibiting enzymes necessary in steroidogenesis.[11] Early experience has shown that it decreases plasma testosterone to castrate levels within 72 hours, and objective response appears similar but not superior to orchiectomy. Although there are no feminizing or cardiovascular side effects, as many as half of patients may have significant nausea, necessitating reducing the drug dosage. Other imidazoles may be developed that have fewer side effects.

Chemotherapy in Prostatic Cancer

Chemotherapy has been reserved primarily for men who are clinically progressing following hormonal therapy. Through the efforts of the NPCP and other groups, several cytotoxic agents have shown efficacy in treating prostatic cancer, including methotrexate, cisplatin, cyclophosphamide, 5-fluorouracil and doxorubicin (Adriamycin) hydrochloride. If such agents are effective in men with end-stage disease, then they might be even more effective in patients with less tumor bulk. This was supported recently by Servadio and colleagues who reported a series of 24 patients with untreated metastatic disease undergoing orchiectomy, followed by administration of DES (3 mg a day), intravenous administration of 5-fluorouracil (10 mg per kg weekly) and cyclophosphamide (10 mg per kg weekly).[12] After two years, the chemotherapy doses were reduced by half and given every three weeks. Servadio and co-workers reported 75% stabilization or regression of metastatic lesions, which is similar to

results of standard hormonal therapy. However, the duration of survival appears to be improved, with a cumulative survival of 51% at six years, compared with a mean reported survival of three years in men with newly diagnosed metastatic prostatic cancer.[6] The NPCP currently is testing methotrexate as an adjuvant to hormonal therapy in men with untreated metastatic prostatic cancer (protocol 1700).

The National Prostatic Cancer Project was organized in 1973 and its initial endeavors focused on men with metastatic disease who had relapsed following hormonal therapy. In 1982 a phase III trial testing intensive outpatient combination chemotherapy in such men was initiated (protocol 1500). The three protocol arms include methotrexate (40 to 60 mg per m^2 given intravenously every two weeks); doxorubicin (50 mg per m^2 given intravenously every three weeks) plus cyclophosphamide (500 mg per m^2 intravenously every three weeks) and cisplatin (50 mg per m^2 intravenously every three weeks) plus 5-fluorouracil (500 mg per m^2 intravenously every three weeks) plus cyclophosphamide (500 mg per m^2 intravenously every three weeks). Toxicity has been acceptable. Preliminary results suggest that all of the treatment arms represent effective chemotherapy in prostatic cancer, with each arm eliciting an objective response rate of at least 50%.[13] With the support of referring physicians throughout the Northwest, our center consistently has led the NPCP in patient accrual. A more intensive phase I study conducted at Pennsylvania State University Medical Center (Hershey, Pa) using aminoglutethimide, cyclophosphamide, doxorubicin and 5-fluorouracil has shown an 81% objective response rate.[14] All of these patients have required some inpatient treatment, and a few have experienced considerable toxic reaction.

Palliative Therapy

Finally, patients who have already received hormonal therapy and are relapsing often have severely painful body metastases. Traditional methods of palliation have included administering steroids, radiation therapy (either directly to the painful site or half- or total-body irradiation), bromocriptine, adrenalectomy and hypophysectomy. More recently an inexpensive method of treatment was presented that may be effective.[15] Etidronate disodium (Didronel) is a diphosphonate and is quite similar in composition to pyrophosphates, which inhibit the precipitation of calcium phosphate and retard the conversion of amorphous hydroxyapatite into crystalline hydroxyapatite. Although pyrophosphates are rapidly inactivated by pyrophosphatase, diphosphonates are highly resistant to enzymatic hydrolysis and are potentially useful in the treatment of metabolic bone disorders. Etidronate disodium is a medication given orally and intravenously that acts primarily on bone and inhibits either bone resorption or bone mineralization. It is an effective, well-tolerated drug for the treatment of Paget's disease of bone,[16] with relief of bone pain in most cases. More recently, it has been reported to be quite effective in nine patients with various malignant disorders, including prostatic cancer, who have painful, bony, metastatic lesions.[15] Although etidronate disodium is not intended to cause disease regression, substantial palliative improvement has been reported. The Section of Urology at our center is participating in a randomized double-blind outpatient trial to determine whether early claims of the effectiveness of etidronate disodium are justified (Table 4).

TABLE 4.—*Etidronate Disodium (Didronel) Double-Blind Study*

Inclusion Criteria
Prostatic cancer with painful bony metastasis resistant to hormonal therapy or manipulation
Bone pain must be severe enough to require 40 grains of aspirin daily or its equivalent for pain relief. Patient does not need to be actually taking the analgesics
Exclusion Criteria
Patient with Paget's disease, which could confuse evaluation of the drug's effect
Serum creatinine level ≥ 2.5 mg/dl
Patients who have undergone irradiation of painful lesions within 4 wk of anticipated initiation of drug
Patients with change in hormonal therapy or chemotherapy within 4 wk of anticipated initiation of drug

Kikuchi's Necrotizing Lymphadenitis

CHERIE S. EVANS, MD; RONALD L. GOLDMAN, MD; HARVEY Z. KLEIN, MD, *and* NEVEA D. KOHOUT, MD, *San Francisco*

Kikuchi's necrotizing lymphadenitis has recently been reported in the United States where it has not previously been recognized. In the past year three cases were seen in a community hospital in San Francisco. The histologic appearance and clinical features were felt to be sufficiently characteristic to be diagnostic.

(Evans CS, Goldman RL, Klein HZ, et al: Kikuchi's necrotizing lymphadenitis. West J Med 1985 Sep; 143:346-348)

Cases of Kikuchi's necrotizing lymphadenitis have been primarily reported in the Japanese literature.[1-3] The few descriptions in the English language literature have also originated outside the United States.[4,5] Recently, Turner and coworkers from Stanford University studied 30 cases of this disorder, 21 of which occurred in US residents.[6] The importance of recognizing the characteristic histologic appearance of this benign lesion is emphasized by the finding that 40% of their cases were originally diagnosed as malignant lesions, and 30% were subjected to further invasive procedures. In the past year we have diagnosed three cases of Kikuchi's necrotizing lymphadenitis in a community hospital. We report them to further document the occurrence of this disorder in the United States.

Reports of Cases

Case 1

A 34-year-old woman presented with a history of several months of painless enlargement of her right cervical lymph nodes. No clues were elicited by her medical history, routine laboratory studies gave normal values and on physical examination there were no other abnormalities found. A cervical node biopsy was done to rule out lymphoma.

Case 2

The patient, a 20-year-old woman, for 1½ months had slightly tender, right posterior cervical lymph nodes and transient low-grade fever. Treatment that consisted of administering cephalexin (Keflex) was unsuccessful. A medical history, routine laboratory studies and remaining physical examination elicited no abnormalities. A cervical node biopsy was done to determine the cause of her adenopathy.

Case 3

A 19-year-old woman for two to three weeks had enlarged right cervical and supraclavicular lymph nodes that did not recede with a trial of antibiotics. She also had a negative medical history, no constitutional symptoms, laboratory studies that gave normal values and results of a physical examination that were normal. A supraclavicular node biopsy was done to rule out lymphoma.

Pathologic Findings

All three nodes measured 1.5 to 2 cm in maximal dimension. The pink-tan cut surfaces showed no appreciable focal lesions. On microscopic examination there was a characteristic pattern of necrosis in each specimen (Figure 1). The capsules were intact and the architecture was variably altered by punctate cortical foci of necrosis. Within these foci, and representing a striking feature, was a conspicuous number of karyorrhectic nuclei, unassociated with a neutrophilic infiltrate (Figure 2). A polymorphous cellular population comprising histiocytes, foamy macrophages and small and large lymphocytes was present in and around the necrotic foci. This infiltrate was, however, notable for its paucity of plasma cells. Granulomatous inflammation and vasculitis were conspicuous by their absence. Stains for acid-fast bacilli and fungi were negative, and no viral inclusions were seen. The remaining nodal tissue contained residual lymphoid follicles with variable follicular hyperplasia.

Discussion

The histologic appearance of the specimens in our cases is identical to that described by Turner and associates and by numerous other authors, primarily in Japan.[1,2,5,6] The lesion

Submitted, revised, November 15, 1984.

Reprint requests to Cherie S. Evans, MD, Department of Pathology, Mount Zion Hospital and Medical Center, PO Box 7921, San Francisco, CA 94120.

consists of sharply demarcated paracortical foci of necrosis with karyorrhectic debris surrounded by a polymorphous mononuclear cell infiltrate. Plasma cells and neutrophils are scarce and there is no discernible granulomatous inflammation or vasculitis (Figure 3). The clinical features are also quite characteristic. Patients were almost invariably young women with cervical lymphadenopathy. None had a significant medical history and there were no systemic signs or symptoms except a transient low-grade fever in one patient. All of our patients remain well, although the follow-up interval ranges from 3 to 12 months, which is probably too short to be meaningful.

Figure 1.—Paracortical punctate necrosis surrounded by polymorphous infiltrate (hematoxylin and eosin stain × 40).

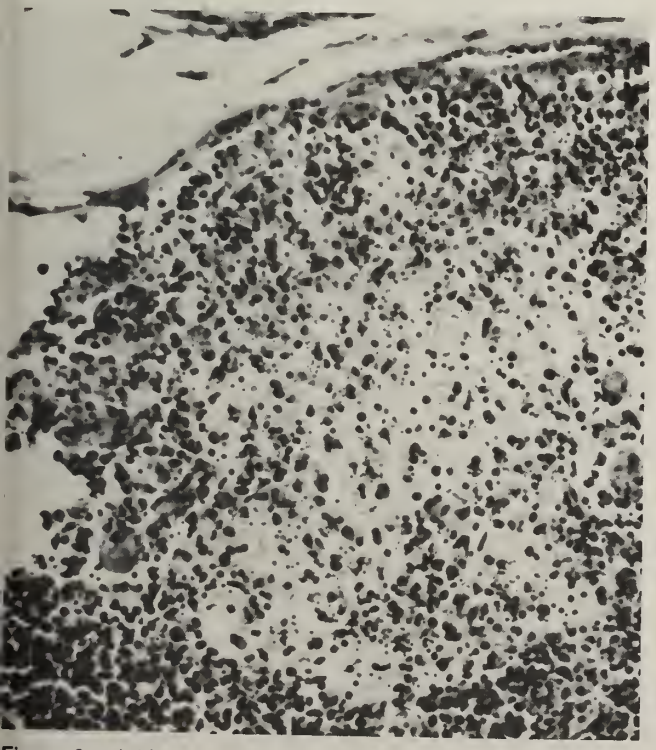

Figure 2.—A higher magnification (× 100) shows paracortical necrosis. Note superficial resemblance to germinal center with necrosis (hematoxylin and eosin stain).

Kikuchi's necrotizing lymphadenitis requires differentiating from malignant lymphoma with areas of necrosis and from other forms of lymphadenitis with necrotic features. In two of our cases the nodal architecture was preserved and was essentially normal. The remaining specimen was more extensively involved by necrotic foci, but residual lymphoid architecture remained intact. The associated cellular reaction around necrotic foci is characteristically polymorphous and lacks obvious nuclear atypia.

Other forms of lymphadenitis with foci of necrosis were considered. However, the histologic features were sufficiently characteristic to rule out animal scratch disease, lymphogranuloma venereum and caseous and gummatous types of necrosis. Systemic lupus erythematosus may present with cervical lymphadenopathy in a young woman. Histologically these nodes may show scattered focal necrosis and a variable percentage of cases will have tuboreticular structures on electron-microscopic examination.[7] The histologic features of the specimens in our cases were distinctly different, however, in that the nodal architecture was generally well preserved, there were no "hematoxylin bodies," the surrounding cellular infiltrate contained only rare plasma cells and there was no evidence of fibrinoid necrosis in the vessels.[7,8] Although none of the specimens was submitted for electron-microscopic examination, we emphasize that the histologic appearances alone, in conjunction with the clinical history—that is, in younger and essentially asymptomatic women—are distinct enough to allow diagnosis.

The cause of this particular form of lymphadenitis remains uncertain and may be multifactorial.[6] Ultrastructural studies have implicated a hyperimmune reaction that is, however, of a nonspecific nature.[7,9] Eimoto and colleagues found tubo-

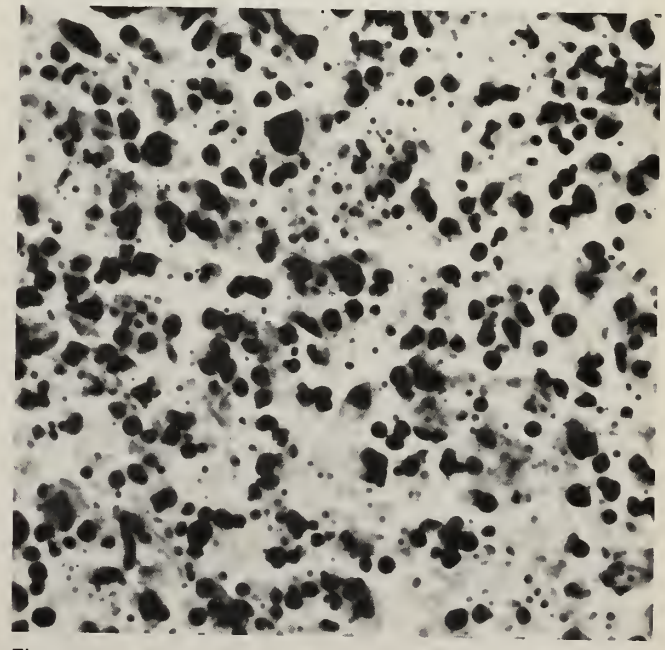

Figure 3.—Karyorrhectic nuclei and polymorphous infiltrate without neutrophils or plasma cells (hematoxylin and eosin stain × 400).

reticular structures and "intracytoplasmic rodlets" in a high proportion of cells in nodes showing Kikuchi's necrotizing lymphadenitis and in another form of necrotizing lymphadenitis with follicular hyperplasia that appears clinically to be a mild collagen disease, possibly related to systemic lupus erythematosus.[7] The recent provocative work of Feller and coworkers, who studied three patients with necrotizing lymphadenitis, should be noted.[4] All of their cases showed infection with *Yersinia enterocolitica*, type 3 or 9, and showed characteristic histologic changes affecting the paracortical T zones, and, more specifically, T-associated plasma cells immunologically characteristic of helper/inducer T cells. However, Kikuchi's necrotizing lymphadenitis does not resemble known cases of *Yersinia*-associated lymphadenitis.[4,6] The work of Feller and associates requires corroboration in future studies, and, as these authors state, not all cases of Kikuchi's necrotizing lymphadenitis seem to be due to *Yersinia*. To date, all reported cases have had a benign course, usually resolving within a few months. Until there is more experience with this disorder in the United States, however, these patients require long-term follow-up.

Finally, as there are other distinct necrotizing processes in lymph nodes, we, along with others, feel that the term "necrotizing lymphadenitis," used by Kikuchi in the Japanese literature, could be confusing and other suggested names have been cumbersome. Therefore, we refer to this lesion as Kikuchi's necrotizing lymphadenitis, as suggested recently by Dorfman and Turner.[10]

Medical Progress

Screening for Developmental Disabilities

CAROL FOSTER, PhD; DEBORAH DURAN-FLORES, MSpEd, OTR; KENNETH W. DUMARS, MD, *and* STANLEY STILLS, MS, MFCC, *Orange, California*

Developmental disabilities are responsible for a combination of severe physical, mental, psychological and social deficits. They develop before age 22 years and involve a little more than 1% of the population. Screening for developmental disabilities is the first step in their prevention. Various screening instruments are available for use throughout the developmental years that are designed to detect the wide variety of developmental problems that interfere with a developing person's optimal adaptation to his or her environment. The screening instruments must be inexpensive, reproducible, widely available and cost effective to the child, family and society.

(Foster C, Duran-Flores D, Dumars KW, et al: Screening for developmental disabilities [Medical Progress]. West J Med 1985 Sep; 143:349-356)

Developmental disabilities are estimated to produce severe impairments in a little more than 1% of the population.[1] Many studies have shown improved outcomes for children with or at risk for developmental disabilities who are provided treatment at very early stages.[2] Because pediatricians and family practitioners are among the few professionals who, as a group, see almost all infants and young children, they play a major role in the early diagnosis of developmental disabilities. Their role in screening for many childhood conditions (for example, the federally mandated Early and Periodic Screening, Diagnosis and Treatment [EPSDT] program on screening for health assessments) is well understood, but their role in screening a child at risk for developmental disabilities is not as well defined. For a program to be effective, the screening procedures should be available for everyone at risk in the population. Ideally, the screening should be accomplished at a single contact with a child or family and with a minimum of cost and time. Unfortunately, a one-time screening effort for developmental disabilities is ineffective because the disabilities may emerge at any time during the developmental period, including the adolescent years, and present with diverse symptoms. A brief overview of the definition of developmental disabilities indicates the complexities of comprehensive screening.

Defining Developmental Disabilities

The category of developmental disabilities was first established in 1970[3] to encompass a broad spectrum of disorders, all of which result in children developing more slowly than their peers, acquiring fewer skills than their peers and requiring extensive support systems throughout their lives. To be eligible for services under the Developmental Disabilities Act, a person must fit the definition of developmentally disabled:

> The term 'developmental disability' means a severe, chronic disability of a person which
> 1. Is attributable to a mental or physical impairment or combination of mental and physical impairments;
> 2. Is manifested before the person attains age 22;
> 3. Is likely to continue indefinitely;
> 4. Results in substantial functional limitations in three or more of the following areas of major life activity:
>   a. Self-care,
>   b. Receptive and expressive language,
>   c. Learning,
>   d. Mobility,
>   e. Self-direction,
>   f. Capacity for independent living,
>   g. Economic self-sufficiency, and
> 5. Reflects the person's need for a combination and sequence of special, interdisciplinary or generic care, treatment or other services that are of lifelong or extended duration and are individually planned and coordinated.[3]

The above definition is a functional one because it identifies how a person carries out daily activities. While each state must follow this definition to obtain the federal funds, some states use slightly different versions. For instance, California uses a combination of categorical (describing the type of disability) and functional approaches. That is, a person with a substantial functional limitation is eligible only if she or he has mental retardation, cerebral palsy, epilepsy, autism or a related neurologic disability.[4]

Purpose of Screening for Developmental Disabilities

In this article we provide an overview of a broad-based screening program and describe the importance of a physician's role in that program.

Screening is the application of a simple accurate method for determining which children in a population are likely to be in need of special services to develop optimally. After screening, one can determine which persons should receive more extensive, more intrusive or more costly diagnostic procedures. Screening procedures should not be viewed as diagnostic, they simply divide a population into those who need diagnostic work and those who are not at risk for a condition. Diagnosis determines the extent and, in some cases, the cause of a disorder and is useful for making placement decisions.[5]

A broad-based screening program must include the functional, categorical and etiologic approaches. If only one or two of these approaches are used, eligible children may not be identified until major delays have occurred. Table 1 provides examples of how children at risk for different conditions may or may not be identified if the screening program assumes only a single definition or orientation.

For example, if one screens only for significant limitations, then phenylketonuria (PKU) will not be discovered until irreparable brain damage has occurred. Also, if one screens only for specific etiologic conditions, then many children with mental retardation, language delay and other conditions of unknown cause would be missed.

Characteristics of Screening Programs

Standard screening procedures should share common characteristics whether they are to screen for tuberculosis or for developmental disabilities. First, the screening procedures should be less costly in time, materials and other resources than the diagnostic procedures. If the resource requirement is essentially equal, then a professional should simply use an accurate diagnostic procedure.

Screening procedures should also be simple. An extremely difficult or painful procedure cannot be justified for every child when only 1 out of 10,000 may have the condition. Conversely, asking a 5-year-old child to respond to the Snellen E chart is simple for both the child and the professional.

A comprehensive program should also incorporate screening for conditions other than developmental disabilities. Including biomedical conditions such as sickle cell disease, psychological problems such as attention-deficit disorder and sociocultural problems such as child abuse greatly enhances the screening program.

Screening is appropriate whenever age of onset and duration of process aggravate or worsen the outcome. As with any behavioral trait, early identification or preventing its occurrence lessens the sequelae of complications. Just as proper eating habits ameliorate the occurrence of obesity and not starting to smoke is easier than stopping, early identification of those mechanisms responsible for failure of attentiveness or learning improves outcome. Medicine has learned that treating a case of tuberculin conversion is easier than waiting for the development of disseminated disease. Placing a newborn on a low phenylalanine diet prevents the occurrence of the devastating consequences of uncontrolled phenylalanine levels.

Related to intervention is the cost effectiveness of the screening procedures. Relatively costly procedures for extremely rare disorders need to be considered carefully. The cost of lead screening on the East Coast has been considered a worthwhile investment because of the incidence of lead poisoning there (Table 2). It is unclear whether or not this is an appropriate activity in many western states where young children's access to lead is limited. However, screening tests adequate for detection should be inexpensive, easily repli-

TABLE 1.—*How a Screening Program Can Be Affected By the Definitional Approach Taken*

Condition Identified	*Type of Definition*		
	*Functional**	*Categorical*	*Etiologic*
PKU	Discovered only after irreparable brain damage has occurred. A child with PKU is identified only when functional limitations are apparent.	Discovered only after irreparable brain damage has occurred. A child with PKU is identified only when mental retardation is apparent.	Discovered through a newborn screening program; damage can be prevented.
Mental retardation	Discovered through screening for functional limitations.	Discovered through screening for functional limitations.	Many etiologic conditions result in mental retardation, but if screening is done only on an etiologic basis, many are missed.
Substantial limitation in language and self-care associated with neglect and not associated with mental retardation, cerebral palsy, epilepsy or autism	Discovered through screening for functional limitations.	Discovered through screening but may not be eligible.	Probably not discovered by screening according to cause.
Lead poisioning	Discovered only after irreparable brain damage has occurred; a person with lead poisoning is identified only when functional limitations are apparent.	Discovered only after irreparable damage has occurred. A person is identified only when mental retardation is apparent.	Discovered through lead screening; further damage can be prevented.

PKU = phenylketonuria

*The functional approach is as laid out in the Developmental Disabilities Act of 1970.[3] In the State of California, functional limitations must be associated with mental retardation, cerebral palsy, epilepsy and autism.

cated and capable of being conducted by a health, educational or psychological assistant. The screening test should be accompanied by a minimum of false-positive and false-negative results. False-negative results (failing to refer persons who have the condition) should be avoided for conditions that are potentially devastating, such as those identified in biochemical newborn screening. Conditions that may result in negative labeling (poor environment) may require a more conservative approach to referral and have more false-negatives. In the latter instance, continued surveillance by a physician is important.

Screening tests imply surveillance of a large at-risk population, together with accurate diagnostic capabilities and effective intervention modalities or strategies. There are situations wherein screening is most successful within a limited population. For example, Tay-Sachs and sickle cell diseases occur in fairly circumscribed groups. A crucial decision is when the screening program should be applied. For example, screening for PKU, galactosemia and hypothyroidism during the newborn period identifies those at risk during the early period when treatment is most effective rather than, for example, screening at the preschool ages. Unless there are earlier clinical symptoms, screening for vision and hearing deficits coincides nicely with children's visits to physicians just before entering school. Referrals for further testing and intervention can follow. Using the latest technology, which will soon be available, screening for Huntington's disease during the newborn or early years is inappropriate for we have nothing to offer those who may be carriers and thus will ultimately be affected.

Screening for behavioral and cognitive end points must be interpreted very cautiously. Screening for development must be a collaborative venture between those testing a child and the child's guardian, usually the parents. A child who generally functions within normal limits may score in the questionable range for reasons of ill health, emotional stress, culture or language barriers. Intervention in the event that a child does not test within the normal range is carried out only after due collaboration with parents, health care providers or educators. This again emphasizes the fact that screening in no way implies a diagnosis, or that it should immediately be followed by an intervention or a prognostication. It should only trigger a mechanism in which a full evaluation of that child is done, including input from parents, guardian caretakers, educators or day-school personnel.

Screening for PKU in California provides an example of procedures that meet these considerations. By screening at birth in the hospital, the program reaches essentially all newborns. In California from October 3, 1980, to August 1, 1985, which includes 1,585,143 tests, there were no missed cases.[7] It requires little effort on the part of hospital staff. All infants with elevated phenylalanine levels are identified by the screening test; 1 out of 34 with an initial positive screen has classical PKU. The cost is $24 per infant tested, which is low when compared with the cost of at least $40,000 per year for adults with untreated PKU.[1] Finally, early diagnosis is extremely important. An effective dietary treatment can be instituted immediately, resulting in the child's maintaining normal intellectual functioning. This is in contrast to children untreated for even the first year of their lives, whose mental development will be retarded. There is a direct relationship between the length of time a child is untreated and the decrease in intellectual functioning.[8,9] Thus, PKU screening is available to all newborns and is accurate, simple, inexpensive and results in early effective treatment.

Recommendations for a Physician's Role in Screening

The physician's role in screening is especially important. As a provider who has regular contact with the family, the physician can monitor a child's development through routine screening. The role of physicians in preventing the occurrence of a developmentally disabling condition will be described at three developmental stages: preconceptual, prenatal and postnatal.

Preconceptual

The health of a newborn is to some extent related to the state of the mother's health. Certain safeguards for a newborn infant can be undertaken by the mother. It is hoped that the mother is in optimal health before and during her pregnancy. Table 3 lists those situations that increase a mother's risk for complications including the birth of a handicapped infant. A physician may wish to screen women for these factors and counsel them accordingly.

Though a mother affected with one of many chronic diseases can deliver a normal infant, there are disorders such as hypertension, diabetes, heart or renal disease and the like that increase her risks for complications. Optimally, before pregnancy all mothers should receive the rubella vaccine or have serologic evidence of rubella immunity (or both). The pres-

ence of genetic disorders and maternal age influence the risks of being delivered of a handicapped infant. It is useful to know the blood and Rh type of the mother and, if the mother is blood type O, Rh negative or both, the father should be tested. In selected populations it is advisable for couples to have reproductive testing for sickle cell disease (in blacks), thalassemia (in Asians and Mediterranean population groups) and Tay-Sachs disease (in Jews).

Prenatal

Wilson[10] has listed genetic and environmental causes of developmental defects, as shown in Table 4.

A note of caution is necessary in interpreting this table. A developmental defect differs from a developmental disability. For example, cleft lip-cleft palate is a developmental defect, but in isolation rarely produces a developmental disability.

Earlier we mentioned the desirability of screening for the hemoglobinopathies and Tay-Sachs disease in appropriate population groups. As part of preconceptual or prenatal care, one should obtain a brief pedigree, inquiring specifically about fetal loss, malformations, mental retardation, short stature, myopathies and neuropathies and common disorders such as cystic fibrosis, Huntington's disease and other late-onset disorders. Based on this information and parental age, the following families must be notified about the availability of prenatal diagnosis for genetic disorders:

- The mother will be 35 years or older or the father will be 55 years or older at the time of the child's birth.
- Either parent has had a previous child with Down's syndrome or another chromosomal abnormality.
- There is a history of a relative with a proved possibly heritable chromosomal anomaly or mental retardation.
- The couple has a history of two or more miscarriages or infertility.
- Either parent carries a balanced chromosome rearrangement (inversion or translocation).
- There is a history of a congenital malformation in either parent or in a previous child.
- There is a family history of a neural tube defect such as spina bifida or anencephaly.
- Both members of the couple are carriers of an autosomal recessive disorder, such as Tay-Sachs or sickle cell disease, thalassemia or PKU.
- The mother is a known or possible carrier of an X-linked condition, such as Duchenne's muscular dystrophy, hemophilia A and X-linked mental retardation.
- Either parent is affected with or has been shown to carry the gene for an autosomal dominant condition, such as achondroplasia, Marfan's syndrome, tuberous sclerosis or neurofibromatosis.
- The mother has insulin-dependent diabetes mellitus, requires medication for epilepsy or has a history of other possible teratogenic exposure, such as rubella, x-ray or certain drug use during pregnancy.
- The parents are consanguineous (blood-related).
- There is reason to suspect fetal abnormality on the basis

TABLE 3.—*High-Risk Obstetric Patients*

- Socioeconomic
  - Age, younger than 18 years or older than 34 years
  - Parity, 0 or more than 4
  - Marital status, unwed
  - Below 125% of poverty level
  - Educational status, less than 12 years
  - Poor conditions for home delivery
- Nutritional
  - Weight falling outside of standard weight range
  - Hemoglobin, less than 10 grams per dl
- Past pregnancy performance
  - Difficult labor, prolonged (longer than 24 hours)
  - Previous cesarean section
  - History of postpartum hemorrhage
- Past pregnancy outcome
  - Fetal death (infant larger than 500 grams [1 lb 2 oz])
  - Neonatal death (infant larger than 500 grams [1 lb 2 oz])
  - Major congenital anomaly (incompatible with extrauterine life)
  - Low birth weight (less than 2,500 grams [5½ lb])
  - Three consecutive abortions (less than 500 grams)
  - Damaged infant (especially neurologic defects)
- Medical or obstetric complication, present pregnancy, including but not limited to
  - Preeclampsia, eclampsia
  - Genital herpes
  - Diabetes mellitus
  - Heart disease
  - Rh sensitization
  - Sickle cell anemia
  - Hemoglobinopathies
  - Renal disease
  - Mental retardation as evidenced by one of the following
    - Previous enrollment in a special education class
    - Evaluation by a state or federal department of vocational rehabilitation
    - Evaluation by a state or federal department of mental disabilities
    - Evaluation by a licensed psychologist
    - Substantial evidence of inability to manage daily self-care
  - Mental illness as evidenced by one of the following
    - Diagnosis from a psychiatrist
    - Evaluation by a mental health center
    - Evaluation by a psychiatric hospital

of other studies (ultrasound, maternal serum α-fetoprotein level or Rh titer).

Within the next 6 months, California will institute a statewide screening program for neural tube defects using maternal serum α-fetoprotein. This will be voluntary and will be carried out at 15 to 16 weeks' gestation. A blood specimen will be drawn in private offices and clinics and then forwarded to central laboratories. This will identify, in the tested mothers, 80% of the conceptuses affected with neural tube defects. The other 20% will not be detected as the sac on the back is covered with normal skin and will not allow the escape of α-fetoprotein-containing cerebrospinal fluid from the fetus to the amniotic fluid and eventually the maternal serum.

The environmental risks listed in Table 4 are self-evident. We cannot emphasize enough the importance of maintaining adequate medical records, especially those related to environmental mechanisms. In light of our present knowledge, environmental agents are responsible for but a small segment of developmental defects and an even smaller segment of developmental disabilities. However, practitioners must be cautious in prescribing drugs during pregnancy because, for a litigious-minded American public, lack of absolute proof that an agent causes a defect is not an adequate safeguard when a physician is faced with a lawsuit in front of a lay jury. We need only cite the enormous settlements awarded to patients and families who have a history of Bendectin* usage during pregnancy or paternal exposure to Agent Orange. These pending settlements occurred despite the fact that neither of these two agents is clearly identified as being embryotoxic.

*A combination drug by Merrell Dow, each tablet of which contains 10 mg of doxylamine succinate and 10 mg of pyridoxine hydrochloride.

Nonetheless, clear record keeping is essential in documenting the need for any drug, along with adequate information given to patients.

Maternal substance abuse, particularly alcohol, is a significant contributing agent to the occurrence of developmental disabilities in offspring. Fetal alcohol syndrome is estimated to be the third most common cause of developmental disabilities, with a frequency of 1:1,000 to 1:2,000 of live-born infants,[11] just a bit less than the incidence of Down's syndrome.

Though recreational and street drugs are not embryotoxic, addicting drugs such as heroin, methadone and so forth certainly produce addiction in newborns and endanger an infant's survival. Cigarette smoking probably does not cause developmental disabilities; infants born to mothers who smoke, however, are often of low birth weight with its attendant risks.

Postnatal

Physicians are the professionals most likely to detect early developmental problems. Table 5 contains recommendations for specific screening tests and their timing from birth through adolescence.

Physicians, or their assistants, should be familiar with these procedures, schedule them on routine visits and monitor each child's development longitudinally. As can be seen from Table 5, there is a variety of screening procedures; they include determinations of cognitive and motor development, nutrition and parenting skills, in addition to a child's physical state (Tables 6 and 7).

If the results of any of these procedures are questionable, the physician should either apply the appropriate diagnostic

procedures or refer to the appropriate agency. The decision for referral depends on the state and how services are provided. In California, referral to a regional center for diagnostic testing initiates the entry into the service system. Other states have other systems. In general, a physician should have colleagues in physical therapy, occupational therapy, social work, nutrition, dentistry, ophthalmology, audiology, speech and language, education and psychology who can cooperate in diagnosis and the development of intervention strategies.

Another important role a physican provides is communication with the family. By treating screening as part of routine pediatric care, the physician will be communicating with the family on the child's development and will be orienting them towards prevention efforts. As the child grows, parents and physician will discuss motor development, the child's response to parents and the use of language. Parents are excellent observers of their children,[17] and discussion with them can augment the physician's perception of a child. In addition, discussions on development will make the need for further testing more understandable in those infrequent instances when it is necessary. Incorporating the parents' observations into the physician's screening results will involve the parents in the decision. More familiarity with development also provides a better basis for encouraging questions and discussion.

A related responsibility of the physician is preparing parents for the diagnostic testing and possible intervention. Parents should be informed of what to expect, how long it will take, whether or not pain is involved, what information will be obtained and so forth. A few minutes of discussion on a procedure such as the auditory evoked potential can greatly reduce apprehension and promote the physician's rapport with the family. The preparation of parents promotes their ability to prepare their child. Better prepared and calmer parents result in calmer children, thus facilitating more accurate results on many diagnostic tests.

TABLE 6.—*Criteria for Eligibility of High-Risk Infants for Regional Center Intervention Services**

- Medical Factors
  - Prematurity (less than or equal to 32 wk)
  - Postmaturity (greater than or equal to 44 wk)
  - Low birth weight (less than or equal to 1,500 grams)
  - Small for gestational age (Lubchenco Scale)
  - Assisted ventilation with persistent respiratory instability, including recurrent apnea
  - Prolonged hypoxemia
  - Prolonged hypoglycemia, hypocalcemia
  - Hyperbilirubinemia (greater than or equal to 15 mg per dl)
  - Seizures or transient neurologic signs (positive or negative) in first 5 days of life
  - CNS hemorrhage, grades 2-4
  - Confirmed correlating infections of the CNS (meningitis, encephalitis)
  - Multiple congenital anomalies requiring special services
  - History of maternal chemical exposure (alcohol, hydantoin, warfarin)
  - Abnormal neurologic findings in premature infants
  - Not significant if
    - atypical tone
    - asymmetry
    - startles and/or tremors
  - Significant if combined with
    - lack of or inconsistent visual pursuit
    - decreased popliteal angle
    - decreased mobility
- Clinical/Behavioral Factors
  - Persistent feeding problems (mechanical)
  - Persistent inability to self-calm
  - Erratic sleep-wake patterns
  - Persistent tonal problems
  - Continued evidence of delay in one or more developmental areas
- Social/Environmental Factors
  - Poor maternal-infant attachment
  - Prior family history of abuse/neglect (parents, other siblings)
  - Neonatal addiction or maternal history of substance abuse
  - Mother's medical or mental condition of a nature to require professional supervision and support to assure necessary child care (severe cerebral palsy, mental retardation, depression, alcohol abuse)
  - Maternal age is 16 years or younger†
  - Lack of or inadequate use of support systems (church, parents)†

In the opinion of an interdisciplinary team—such as a hospital discharge planning team or a Regional Center Developmental Disabilities intake team—the infant is considered to be at high risk for becoming developmentally disabled.

CNS = central nervous system

*Report of the Association of Regional Center Agencies Prevention Task Force.[16]
†May not be used as a single criterion.

Schools

The physician's involvement with the educational system is important because of the federally mandated screening program. Nationally, the federally mandated EPSDT pediatric screening program is designed as an ongoing federally funded source of medical checkups and care for all persons, 0 to 21 years of age, enrolled in a state medicaid program, namely, that for low-income families.

California operates its version of this program, Child Health and Disability Prevention (CHDP), which, as of 1981, includes EPSDT services and state-supported screening only, not diagnosis and treatment, for "income-eligible, non-MediCal" children.

TABLE 7.—*Normal Ages of Appearance and Disappearance of Neurologic Signs Peculiar to Infancy**

Response	*Age at Which Normally Appears*	*Age at Which Normally No Longer Obtainable*

Parachute reaction	8-9 mo	Variable

*From Paine.[15]

The national EPSDT screening model promotes an interest in identifying recognizable pediatric disorders that interfere with health and development. The screening periodicity chart (see Table 5) indicates that a developmental history and assessment is a part of health-assessment procedures required of an examiner at each of the age levels, from birth through 21 years. All practitioners can obtain developmental data from simple techniques and communication skills.

A Denver Developmental Screening Test (DDST)[14] is the standard tool used by pediatric nurse practitioners and physicians to assess development in children from birth through age 6 years. Beyond 6 years of age, medical tests, clinical observations, home-school psychosocial adaptation and knowledgeable judgment are the health professional's tools of developmental assessment. The newly revised DDST, the DDST-R, is less time-consuming than earlier versions. Specifically, 12 items or fewer are all that are necessary to obtain a result on children up to the age of 6 years. Even more simply, a prescreening developmental questionnaire[13] can be given to parents to complete in a few minutes. It is a "prescreening" tool designed to select those children who should have a complete DDST. This questionnaire is extremely short and simple and uses parental reports. It can discriminate developmental lags and suggest more detailed screening. In later ages, collaboration among health and education professionals and parents is essential for an effective and efficient use of a physician's time. While most abnormalities are minor, pediatric nurse practitioners, on screening students in schools, do regularly refer children with greater health and developmental manifestations for possible diagnosis and treatment.

For a child identified after age 6 years, referrals to a special education program originate primarily from teachers, parents, nurses and classroom aides, but at present relatively few from physicians. A typical "child-study team" might be the first level of response to a referral. Consisting of an administrator, a registered nurse, the child's classroom teacher and an appropriate professional evaluator, the team will review a child's level of performance and determine possible eligibility for special education services. If so determined, a second-level assessment strategy will be orchestrated to obtain various evaluations and pertinent information for use in deciding on the most appropriate special education services. Participants on this latter team may include school personnel, outside physicians and clinics, therapists and parents. Following attaining their findings, an Individual Education Plan (IEP) is written by school district personnel, the classroom teacher, parents and others who will delineate the following: the special services required, such as diet, transportation, nursing care; the classroom environment for placement (a special day class, a resource specialist), and teaching objectives and methods planned for an individual child—that is, academic, vocational, sign language or braille. An annual review and a three-year follow-up IEP meeting shall follow to evaluate case management.

The message to physicians from professionals in the fields of early childhood education and special education is to be aware of what a public school can and cannot do, along with what a medical practitioner can and cannot do. Basically, local school districts are able to take referrals on a child and determine a student's eligibility for certification as a "child with exceptional needs" for any child between the ages of birth and 21 years. They can also coordinate this process for the child and parents.

The physician can request an assessment of the child's performance and eligibility for "special services" by contacting a county Office of Education, local school district office or a school principal. A physician should look with sensitivity and scrutiny at a child's developmental history and current state and should engage the child *and* the parents in obtaining information to document physical and behavioral elements of each young patient. Physicians can cooperate by communicating via records and personal correspondence to schools, professionals and parents and can become providers of service in the state EPSDT program. Physicians cannot make promises to parents of educational services and special education placement and cannot be negligent by excusing parental concerns and clinically suggestive signs as "something the child will grow out of."

Concerned professionals should make a concerted effort toward an ongoing exchange of information about possible and known exceptional needs of children. The treatment and education of a child with special needs of a physical or a mental nature require the roles of various personnel. Unless all professionals share information and decisions for appropriate intervention, optimal comprehensive care will be unlikely.

Characteristic of uncoordinated client activities are fragmented interventions, gaps in service delivery, costly duplication and ill-advised services, poor child adaptation and parental and professional frustration. A team approach can guard against such problems and ensure that each child is given the opportunity to develop to his or her maximal potential.

Measures of Effectiveness

Evaluating any major social program such as screening for developmental disabilities has some major problems. We propose three general categories for evaluating the effectiveness of screening programs: quality of life, the incidence of developmental disabilities and the cost to society. These range from extremely subjective to quite objective. The most subjective, but perhaps the most important, is improved quality of life for a person and family. While having a developmental disability does not reduce the worth of a person, most people would agree that a developmental disability creates many personal, family and societal problems. Weikart[18] reported a reduction in several major social problems, including teenage pregnancy, unemployment, detention and arrest and welfare assistance for children who had been in a Head Start program 14 years earlier.

Another effectiveness measure that is more scientific but still difficult to obtain is the incidence of developmental disabilities. Determining the reduction in incidence of discrete conditions such as infants with rubella syndrome is complex but can be done with considerable accuracy.[19] The problems with ascertaining decreases in developmental disabilities are exacerbated by several issues. First, developmental disabilities represent a collection of conditions of both known and unknown causes. Due to the different definitions, this collection changes from state to state and even with the diagnostic instrument used. This changing definition creates difficulties in making comparisons across locations and time.

Another difficulty in evaluation is that the definition is relatively new. Since the category was created in 1970, there are no longitudinal data available. Related to this is the fact that because more money and more programs are available for persons with this diagnosis, more are identified.

Still another difficulty is presented by the fact that developmental disabilities can emerge any time during the developmental period. Thus, determining the counts at times when infants and children can be more easily evaluated, such as in screening for PKU at birth, may miss many children affected with other disabilities.

A more concrete measure of effectiveness can be found in ascertaining the cost of various conditions to the state or to the family. All states except two have mandatory screening for PKU, which affects about 1 in 17,000 births. In California, about 20 to 25 cases are detected each year.[7] Since 1966 when the program began, there has not been a single admission to the state hospital system. A conservative cost-benefit analysis shows that about $7 are saved for every dollar spent.[7] Estimates of how much the care of a child with developmental disabilities costs above that for a child without this condition are available. For example, according to the California State Council on Developmental Disabilities, it costs $360 per month to keep a child of 3 years at home (James Shorter, Executive Director, written communication, August 1984). The cost varies with size of family, age of child and gross income. If a child has a developmental disability and is placed out of the home, the cost can be as high at $6,000 per month (J. Shorter, written communication, August 1984).

The effects of screening and early intervention have also been documented through cost analyses. Children who received two years of preschool saved more than seven times the cost of the preschool for their public education compared with a matched control group.[18] Wood[20] analyzed costs and found that the cost of education for 940 multiply handicapped children depended on the age at which intervention was started. The cost was $37,273 for children who began programs at birth, compared with $45,816 for those who started at age 6 years.

The human impact is even more important than the financial aspects. The High/Scope Education Research Foundation found that children in the Head Start program experienced changes that were evident even after 12 years of public school. These children were more likely to finish high school, get a job, enroll in postsecondary education and score well on tests of functional competence than their matched peers who had not attended Head Start.[18] They were less likely to require special education, be arrested, be on welfare or become pregnant during the teen years. Other studies have shown changes in intelligence,[21] ability to adapt to regular education[22] and the ability to be self-supporting.[23,24]

Another area where early intervention has proved to be quite effective is in follow-up programs for high-risk infants from neonatal intensive care units. In California where these projects have been conducted on a pilot basis, there are significant reductions in child abuse, in the length of the original hospital stay and in the rate of readmission to hospital.[25]

Specialty Conference

Lead Intoxication in Children

Moderator
WILLIAM L. NYHAN, MD, PhD

Discussants
MARK SAWYER, MD; THOMAS KEARNEY, PharmD; SAMUEL SPECTOR, MD, *and* SASKIA HILTON, MD

From the Departments of Pediatrics and Radiology, University of California, San Diego, Medical Center and School of Medicine, and Regional Poison Center Emergency Medicine Services, San Diego.

WILLIAM L. NYHAN, MD, PhD:* *Lead poisoning continues to be a significant source of morbidity in children. Promptly recognizing early symptoms and combining effective chelation with the removal of lead from a child's environment are associated with a good prognosis. Therefore, it is important for physicians to be alert to the possibility of this diagnosis. At the same time, although it is often thought that this is a problem found exclusively in the residents of very old buildings in the inner cities of the eastern part of the country, children in the West do get exposed to lead. There are even some unique or at least novel ways in which this takes place.*

Our experience with lead intoxication is increasing. In the period from July 1, 1983, through September 30, 1984, five patients with lead poisoning were admitted to the University of California, San Diego (UCSD), Medical Center. The reasons for this are probably complex and are not completely clear. In the cases to be presented at this conference, two of which are described in detail, the mechanisms of intoxication were well defined, but this is not always the case. Possibly more children are now living in old inner-city buildings in San Diego.

Reports of Cases

Case 1

MARK SAWYER, MD:† Two patients with lead intoxication were admitted to Childrens Hospital during the past year. The first, an 8-year-old Mexican girl, was well until a week before admission when abdominal pain developed. This was followed by fever, nausea and frequent emesis. She was treated with aspirin and ampicillin. On the day before admission she had a generalized seizure. She was initially admitted to hospital in Mexico. During the evening before admission her level of consciousness decreased and she became combative. She was given dexamethasone and transferred to Childrens Hospital in San Diego. It was learned that she lived next to a battery-processing plant in Mexico.

On physical examination she was lethargic but combative and appeared small and malnourished. Her respirations were 20 per minute; pulse 120 beats per minute and blood pressure 160/110 mm of mercury. Temperature was 37.9°C (100.2°F) rectally. She weighed 23 kg (51 lb). The pupils reacted sluggishly to light but the fundi were normal. The abdomen was soft. Her gaze was disconjugate. Results of a cranial nerve examination otherwise showed no abnormalities and sensorimotor findings were normal. Reflexes were normal. Laboratory evaluation showed a blood lead concentration of 62 μg per dl and a free erythrocyte protoporphyrin (FEP) value of 316 μg per dl of whole blood. Hemoglobin was 12.6 grams per dl, hematocrit 34% and mean corpuscular volume (MCV) 80 cu microns. Basophilic stippling was present in the erythrocytes. The leukocyte count was 18,300 per μl with 84% polymorphonuclear leukocytes, 7% bands, 8% lymphocytes and 1% monocytes. The specific gravity of the urine was 1.018 and there were 3 + ketones, 1 + blood, 2 to 5 leukocytes and 0 to 2 erythrocytes. The blood urea nitrogen (BUN) level was 20 and creatinine 1.1 mg per dl. The cerebrospinal fluid concentration of glucose was 92 mg per dl and protein 20 mg per dl; there was 1 lymphocyte.

An endotracheal tube was inserted, she was hyperventilated and an intracranial pressure monitor was placed. A computed tomographic scan of the head showed small ventricles suggesting diffuse edema. The initial intracranial pressure was 40 torr. It responded rapidly to treatment with barbiturate and mannitol and was easily maintained at less than 20 torr. Chelation therapy was begun using dimercaprol (BAL), 600 mg per day (720 mg per m^2), and edetic acid (ethylenediaminetetraacetic acid [EDTA]), 1,800 mg per day (2,170 mg per m^2), for five days. Her urinary excretion of lead was 3.7 mg per dl during the first 24 hours of therapy. The blood concentration of lead ten days after chelation therapy was 22 μg per dl. An electroencephalogram showed

ABBREVIATIONS USED IN TEXT

BUN = blood urea nitrogen
EDTA = edetic acid (ethylenediaminetetraacetic acid)
FDA = Food and Drug Administration
FEP = free erythrocyte protoporphyrin
MCV = mean corpuscular volume
UCSD = University of California, San Diego

generalized slowing. Treatment was continued with phenobarbital.

She was seen three months after discharge and had a blood lead concentration of 42 μg per dl and an FEP value of 424 μg per dl. She had evidence of peripheral neuropathy with left foot drop. A sample of water from her home supply had an extremely high lead content.

Case 2

The patient, a 15-month-old Mexican female infant, was in excellent health until two months before admission when diarrhea developed. She was initially treated with ampicillin and after failing to respond was given azarcon for five days. Her 3-year-old sibling was given the same medication, progressive lethargy and vomiting developed and she died two weeks later. For this reason, this child presented for evaluation. Although she was asymptomatic, her blood lead concentration was 124.5 μg per dl and the FEP value was elevated.

On physical examination on admission she was well developed and well nourished, her height was 64.5 cm and weight 10.4 kg (23 lb). Blood pressure was 100/45 mm of mercury, respirations 32 per minute, pulse 116 beats per minute and rectal temperature 38°C (100°F). The fundi were normal. The abdomen was unremarkable. She was alert and cooperative, and the sensorimotor examination elicited no abnormalities. Deep tendon reflexes were 2+ and symmetric and the cranial nerves were intact.

Laboratory evaluation elicited the following values: a hematocrit of 31.3%, hemoglobin 9 grams per dl, MCV 63 cu microns, mean corpuscular hemoglobin 18.6 cu microns, mean corpuscular hemoglobin concentration 29.7% and platelets 461,000 per μl; leukocytes were 14,900 per μl, with 33% neutrophils (2 bands), 58% lymphocytes, 4% monocytes and 2% eosinophils. Basophilic stippling was present. The reticulocyte count was 0.8%. The urine specimen showed a specific gravity of 1.020 and tests for protein, glucose and blood were negative. BUN was 16 mg per dl and creatinine 0.5 mg per dl.

Treatment was started with dimercaprol, 240 mg per day (800 mg per m^2) for three days, and EDTA, 390 mg per day (1,300 mg per m^2) for five days. Her blood concentration of lead fell to 61 μg per dl after five days of therapy. After discharge she received penicillamine, 375 mg per day (36 mg per kg of body weight per day), for five months. Her blood lead concentration at the time of discharge was 41 μg per dl.

Sources of Lead Contamination

DR NYHAN: *Dr Kearney will now present some very interesting information he has uncovered on the sources of the intoxications in these two children.*

THOMAS KEARNEY, PharmD:* Of paramount importance in the management of lead poisoning is identifying the source of the lead. These cases show some unusual sources of lead contamination in patients coming from Mexico. Of course, these hazards may affect our own citizens visiting Mexico and those who live here but who share cultural backgrounds with those across the border.

The causative agent in one patient was azarcon, which can be purchased in Tijuana. Azarcon is a bright orange powder used by the local folk healers or *curanderos* to treat nonspecific gastrointestinal symptoms known collectively as *empacho*. Azarcon is essentially 100% lead tetroxide and has a 90% content of elemental lead. There have been numerous instances of lead poisoning attributed to the use of azarcon reported in California and in Colorado.[1,2]

We recently carried out a screening project for lead on 100 Hispanic children in a San Ysidro clinic. The parents of the children screened for lead were surveyed with respect to their knowledge and use of folk remedies. A significant percentage of the parents (more than 10%) knew of azarcon and most of them said that they would consider using this substance for the treatment of *empacho* in their children.

*Clinical Toxicology Fellow, San Diego Regional Poison Center, Emergency Medical Services, UCSD Medical Center.

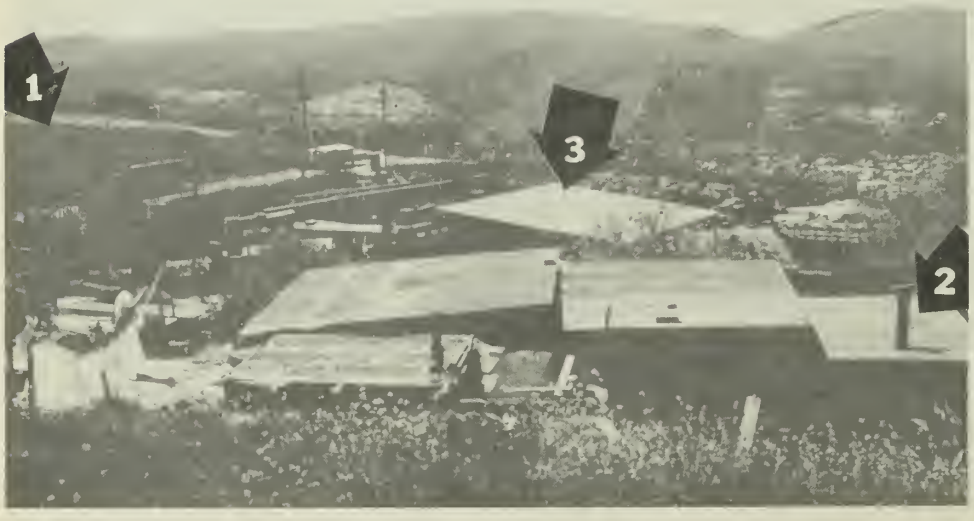

Figure 1.—La Gloria is a rural community located on a hillside. Adjacent to the community is the Rotary Club (arrow #1) where the horses died. This is a view looking down on the patient's residence (arrow #2). Arrow #3, battery recycling plant.

Apparently it is common practice among the Mexican-American community to seek medical attention from a folk healer or *curandero* in Mexico for the treatment of *empacho*. The folk healer usually resorts first to herbal teas in the treatment of diarrhea but administers azarcon in refractory cases. To increase the palatability of azarcon, it is usually mixed with an herbal tea or administered in dry powder form with sugar. The substance administered to our patient admitted to University Medical Center was a fine yellowish powder. This suggests that it may be lead oxide instead of lead tetroxide. Toxicologic analysis by atomic absorption spectrophotometry showed a 95% content of lead. This form of lead has been referred to as *greta*. The Food and Drug Administration (FDA) has reported that *greta* has been imported from Mexico and has been sold in Hispanic communities throughout southern Texas, Florida and California.[3] Other names such as *rueda, Maria Luisa* and *coral* have been given to these lead-containing folk remedies. The Centers for Disease Control have recommended that if patients of Mexican origin present with anemia, abdominal pain, peripheral neuropathy, encephalopathy or renal disease, lead poisoning from these home remedies should be considered in the differential diagnosis.[1]

Figure 2.—The residents just before our arrival had been warned about the potential for contamination of water and were drinking bottled water. The middle barrel in the figure held the drinking water primarily used by our patient.

In the first patient, the only relevant history at the time of admission was that the patient resided in close proximity to a battery recycling plant. Information was obtained that a Rotary Club that was also located nearby had reported that a couple of horses had died. This patient became our index case and it was imperative to identify the source of lead contamination, not only to prevent reexposure but to identify others at risk. A Mexican physician and I, with the assistance of a relative of the patient, did an on-site investigation of the patient's residence. The patient lived about ten miles south of Tijuana in a community known as La Gloria. As we drove in, we saw piles of batteries stacked 3 to 6 m (10 to 20 ft) in height all along the roadside leading up to the patient's residence (Figure 1).

Looking down on the patient's residence, we noted that there was a complete lack of electricity in the area and water was obtained primarily from collected rain water and stored in barrels and cisterns (Figure 2). Rain water was collected also on the roof, ran down a trough into barrels and was the primary source of water for drinking, bathing and other needs. The patient's house was located 46 m (50 yd) from the battery recycling plant. We interviewed the patient's grandmother and some neighbors. We looked for other possible sources of lead contamination in the home such as paint chipping from the wall or the use of earthenware pottery but found none.

In a survey of the neighborhood, we found that many children were experiencing nonspecific gastrointestinal symptoms and they had complained also of acid burns on their feet from open pools of discarded battery acid near the plant. The residents of the area had previously owned a variety of livestock, which had recently died. We also noticed a number of dead birds around the community.

The battery recycling plant used an open furnace to melt down the battery matrix. The impurities were separated from the molten matrix and the lead re-solidified and sold to a battery manufacturer. The exhaust pipe from the furnace was pointed directly at the patient's residence, fewer than 64 m (70 yd) away (Figure 3). The residents did complain about a

Figure 3.—The patient's house was located only 46 m (50 yd) from the battery recycling plant, Metales y Derivados de Tijuana. The plant used an open furnace to melt down the battery matrix. Note that the exhaust pipe from the furnace is pointed directly at the patient's residence less than 64 m (70 yd) away. Arrow #1, Rotary Club; arrow #2, cistern for water storage; arrow #3, furnace.

metallic taste, choking and coughing during the operation of the plant as well as discoloration of the soil.

Located in front of the house, near the plant, was a cistern that served as another storage area for drinking water for the family and its livestock. A specimen of this water was obtained from the cistern. A water sample was obtained as well from a neighbor's cistern because another child there had complained of gastrointestinal symptoms. The family before our arrival had been warned about the potential contamination of their water and were drinking bottled water. A specimen was obtained from the barrel containing rain water, and a final specimen was taken from the bottled water they were presently using.

Analysis of the lead content in the samples was done by atomic absorption spectrophotometry. For a frame of reference, San Diego water contains less than 1 μg per dl of lead. Analysis of the water samples from the patient's residence showed the following:

	Lead Content (μg per dl)
Front cistern	153
Barrel	1,080
Bottled water	4
Neighbor's water	69

It was reasoned that airborn lead effluent from the open furnace contaminated the water supply. We contacted public health officials and this resulted in closure of the plant.

Radiology

DR NYHAN: *Roentgenographic aspects will next be considered by Dr Hilton.*

SASKIA HILTON, MD:* Lead toxicity may cause a confusing array of gastrointestinal symptoms, including abdominal pain, anorexia, nausea and vomiting and constipation.[4] Unfortunately, unless symptoms of involvement of the central nervous system develop or a suggestive history is elicited, the nonspecific gastrointestinal complaints rarely point towards the diagnosis. Occasionally, plain films of the abdomen are taken for the evaluation of gastrointestinal symptoms and the films show paint chips or other evidence of pica such as ingested dirt or plaster. In our third patient, *greta,* the material administered, is readily visualized.[5] It is fortunate that most children with plumbism ingest the substance containing lead, as the lead is often radiographically visible. Identifying the site of the lead is often therapeutically helpful, especially if some or all of recently ingested lead remains in the gastric fundus and thus is available for removal by gastric lavage. In most cases, the offending agent is identified in the colon and can be removed by enema. Water enemas may be contraindicated in patients with increased intracranial pressure, but enemas can be undertaken using a hyperosmolar contrast agent. Fluids are drawn into the colon and mild stimulation of the colon results in evacuation. Patients with cystic fibrosis and

*Associate Professor of Radiology and Pediatrics, UCSD.

Figure 4.—*Greta* is seen throughout the colon to the level of the splenic flexure. Numerous metallic densities of different sizes indicate that a large amount of lead is present in this patient.

Figure 5.—This supine x-ray film of the abdomen was taken of a 3-year-old boy who had ingested lead-based plaster. Densities are seen throughout most of the colon.

severe constipation or even intestinal obstruction are successfully treated with hyperosmolar enemas and so are neonates with meconium plug syndrome.

Plain films of the abdomen in the third patient (Figure 4) showed a large amount of mottled metallic density throughout most of the colon. The high lead content of *greta* is responsible for this appearance. The appearance differs from that in another patient we recently saw who had ingested plaster containing lead-based paint (Figure 5). Use of lead-based paint for commercial surfaces has greatly tapered off since about 1960. Interstate shipment was banned in 1977. However, fresh paint in older buildings does not protect children against ingesting plaster soaked with lead deposited from earlier coats of paint.

Discussion

SAMUEL SPECTOR, MD:* I thought when I left the Midwest that I would no longer encounter lead encephalopathy. Therefore it is surprising that we are discussing the cases of two patients seen at Childrens Hospital in San Diego and currently there is another patient at the UCSD Medical Center. Two of these three patients have shown clinical encephalopathy.

The patient recently admitted to the UCSD Medical Center is an 8-year-old Hispanic boy who had been receiving *greta* for one month before admission because of chronic abdominal discomfort. On admission, he was lethargic, hypertensive and constipated. He could not recall his home address or his telephone number, both of which he had known in the past. His blood lead concentration was 92 μg per dl.

The relationship of lead poisoning to environmental contamination has been well documented over the centuries. It is interesting to review the lead content in the sequential layers of ice in Greenland to obtain a profile of atmospheric contamination over time. At the beginning of the industrial revolution in about 1780, a gram of ice contained about 10 pg of lead. In 1980, levels reached 200 pg per gram, with the greatest increase occurring after 1940. In addition, the lead:calcium ratio of human bones from premetallurgic Peru, when compared with those of contemporary American adults, showed a 200-fold to 600-fold increase.[6] In this country, 1½ million tons of lead are processed each year, primarily in the manufacture of batteries and, secondly, in the petroleum industry in producing leaded gasoline. Lead poisoning as a major problem in children became evident initially in our inner cities. The reason was poor housing in which old, peeling internal paint contained high concentrations of lead. One flake could contain as much as 100 mg of lead. Between 1960 and 1966 in New York and Chicago, 3,339 patients were found to have lead poisoning, chiefly preschool children who had pica. The mortality rate was 8%. It is most upsetting that some 20 years later, screening of 500,000 urban children in 1981 still disclosed 23,000 children with lead poisoning. Although the lead content of paint is currently limited legally to less than 0.06%, old buildings with old, peeling paint remain. Dust has become an added factor, from destruction of buildings and exhaust emissions generated by heavy traffic. Dust contaminates the soil and vegetation and in small children it is placed in the mouth and also inhaled. In the most recent National Health and Nutrition Examination survey between 1976 and 1980, it was found that 4% of all children aged 6 months to 5 years in the United States had a toxic lead concentration in the blood of more than 30 μg per dl. The figures were 2% in rural areas and 11.6% in the inner cities.[7] An unexpected finding was that black people of all ages had significantly higher lead concentrations in their blood. Mean lead concentration in the total population was 14 μg per dl. Black preschool children in an urban setting had an average level of 22.9 μg per dl, compared with white children in whom the value was 18.1 μg per dl.

In reviewing sources of lead in the environment, the data of Chisolm and Barltrop are very useful (Table 1).[8]

In adults, 5% to 10% of ingested lead is absorbed from the gastrointestinal tract. In small children, absorption approaches 40%. In both children and adults, 40% of inhaled lead is absorbed from the respiratory tract. Furthermore, adults can excrete maximally as much as 500 μg of lead daily, while toddlers can excrete only 30 μg a day. Thus, it is clear that children have a special vulnerability. The nature of the sources and the behavior of young children who put virtually anything in the mouth explain why lead poisoning is predominantly a problem of the young. The first patient presented at great risk because she lived in close proximity to a battery factory. There was documented contamination of the water

TABLE 1.—*Sources of Lead in a Child's Environment**

Food
Mixed diet—mean 9.43 μg/kg/d (range 53-132 μg/d)
Bottled baby food—mean 35 μg/liter
Human milk—6-59 μg/liter
Contaminated Sources
Tinned baby foods—mean 202 μg/liter
Cold drink in glazed pottery mug—2,000 μg/liter
Bone meal (health food)—60-190 μg/gram
Paint chips—may contain as much as 100,000 μg/gram
Water
Standards: World Health Organization —<100 μg/liter
Public Health Service (USA) —< 50 μg/liter
Contaminated Sources
Up to 1,850 μg/liter
2,595 samples—1.4% >50 μg/liter, maximum 640 μg/liter
Air
Usual lead content—1-2 $\mu g/m^3$
Contaminated Sources
Smelter A, within 1.6 km— 8-10 $\mu g/m^3$
Smelter B, within 4.0 km—14-16 $\mu g/m^3$
Soil
Remote areas—2-200 μg/gram
Contaminated Sources
Within 1.6 km of smelter—mean 7,600 μg/gram
Urban residential—9-7,890 μg/gram, mean 585 μg/gram
City parks—194-3,357 μg/gram
House Dust
New inner-city homes—2-24 $\mu g/ft^2$ floor surface
Contaminated Sources
Old inner-city homes—33-486 $\mu g/ft^2$ floor surface; mean 11,000 μg/gram[2]
Homes of lead smelter workers—mean 2,687 μg/gram
Homes within 1.6 km of smelter—mean 22,191 μg/gram
Homes located 1.7-3.2 km from smelter—mean 2,124 μg/gram

*Adapted from Chisolm and Barltrop.[8]

*Professor of Pediatrics, UCSD Medical Center.

supply in that the cistern contained 153 μg per dl of lead, and water from the rain barrel contained 1,080 μg per dl. The standard for safe lead levels in water proposed by the World Health Organization is less than 100 μg per liter and that recommended by the US Public Health Service is less than 50 μg per liter. Investigators who visited the home did look for lead-glazed pottery because it is commonly found in Mexico, and cola drinks or fruit juices are excellent vehicles for the dissolving out of the lead from such containers. The usual lead content of air is about 0.5 to 1.0 μg per m^3 and accounts for absorption of about 0.5 μg. It is higher in smog-contaminated areas. In a study in 1976 it was reported that within 1.6 km of a lead smelter stack in Idaho, the air contained 10 to 17 μg per m^3, and 99% of the children younger than 5 years in that radius had toxic lead concentrations in the blood.[9] In 20% of preschool children, the concentrations were above 80 μg per dl, which put them at risk for encephalopathy. In addition to the lead in inhaled air, dust was a larger factor because it is not only inhaled but reaches the mouths of smaller children through hands contaminated with dust and dirt. Soil samples had a lead content of 7,600 μg per gram.

In the second patient and in the third patient recently treated at the UCSD Medical Center, the intoxication was due to the use of a home remedy containing lead. The clinical signs of lead poisoning are vague and the physical findings nonspecific, so a high index of suspicion is required. As these cases indicate, a solid, careful history that includes discussion of remedies that have been used can be very useful in pointing to the diagnosis. In Mexican and Mexican-American patients, the possibility of lead ingestion from this source must be kept in mind.

Toxic Concentrations of Lead

It is of interest to consider the concentration in the blood at which lead is actually toxic. It is probably toxic at any concentration. In experiments on rats, sustained blood lead levels of 10 μg per dl produced renal lesions. The Centers for Disease Control recently have defined a concentration of lead of 24 μg per dl in whole blood as the upper limit of normal for humans. They also have developed a risk classification for asymptomatic children (Table 2),[10,11] which is based on the concentrations of lead and the FEP in the blood. The children in class I are at low risk. Patients in class Ia, in whom the FEP value is elevated but the lead content normal, would be expected to have iron deficiency or erythropoietic protoporphyria. In cases of iron deficiency anemia, the FEP value ranges from 50 to 250 μg per dl. Patients in class Ib, in whom there is an elevated content of lead along with a normal FEP value, usually have a problem with lead that is receding. In class II are children at moderate risk who should be removed from the source of intoxication and rechecked every three months for at least a year. Those in class III are at high risk. They may need further studies concerning lead burden before chelation therapy. Children in class IV and those in class III in whom there are symptoms consistent with lead poisoning are at urgent risk and require chelation therapy.

TABLE 2.—*Risk Classification for Asymptomatic Children**†

Blood Lead Content μg/dl	Free Erythrocyte Protoporphyrin (μg/dl)			
	<34	*35-109*	*110-249*	*>250*
<24	I	Ia	Ia	EPP
25-49	Ib	II	III	III

†Classes I through IV represent increasing degrees of risk or morbidity and are discussed in the text.

‡Combination of results not generally observed in practice; if observed, retest with venous blood specimen immediately

The pathogenesis of lead poisoning begins usually with the ingestion of lead and its absorption from the gastrointestinal tract. Thereafter the lead enters the liver where some is excreted in the bile and the rest enters the systemic circulation. It is deposited chiefly in bone. A lesser amount goes to the soft tissues, such as the erythrocytes, liver, pancreas, kidney and brain. In bone, the content of lead may be six to ten times that in soft tissues.

In bone, lead is handled like calcium; it is deposited as the tertiary phosphate. Factors that favor the deposition of calcium or its release affect lead similarly. Thus, acidosis leads to the mobilization of lead from the bones and may elevate circulating levels of lead, causing symptoms. At the epiphyseal zone, lead produces damage to the osteoid; it is this process that increases density and eventually accounts for the lead lines seen on roentgenographic examination of the bones. The line is not due to the lead itself.

In the soft tissues, lead is a potent inhibitor of enzymes. It has a special affinity for mitochondrial membranes. Erythrocytes have the advantage of ready availability and serve not only the quantitative assessment of the amount of lead in the body but also the functional measurement of clinical toxicity. The FEP test is the most commonly used and is rapidly and easily carried out. Lead blocks two steps in the synthesis of heme (Table 3).[4] The first step inhibited is the conversion of δ-aminolevulinic acid to porphobilinogen; the second is the addition of iron to protoporphyrin. It is this second block that accounts for the increase in free erythrocyte protoporphyrin that forms the basis of the FEP test for the screening of persons for lead poisoning.

In the kidney, lead produces a characteristic lesion in the proximal tubule and the loop of Henle. On microscopic examination there are round, refractile, acidophilic intranuclear inclusions. Clinically, there is a Fanconi syndrome in which there is proteinuria, glycosuria, phosphaturia and general aminoaciduria. Our third patient had proteinuria and glycosuria, and initially it was thought that his disorder was primarily renal. In lead poisoning, the renal lesion is usually reversible.

Involvement of the brain is the most critical element in the intoxication caused by lead from the point of view of both survival and sequelae. Encephalopathy is the usual manifestation in childhood; in adults it is peripheral neuropathy. It is of interest that similar findings are seen in experimental animals. In rat pups, lead enters the mitochondria of the brain where it inhibits respiratory enzymes. In adult rats, lead does not pass the blood-brain barrier. In children, lead entering cortical cells of the brain disrupts mitochondrial function and is responsible for the encephalopathy, which is manifested clinically by seizures and coma. Coma may be seen in the absence of cerebral edema. Edema occurs late, aggravates the situation and becomes life threatening. At necropsy, the brain usually shows intense edema, widespread vascular damage

and degenerative changes. Children with blood lead concentrations in the range of more than 70 μg per dl are at high risk. The first patient, who had coma and seizures, had a blood lead concentration of only 62 μg per dl.

The impact on the developing brain of low levels of lead in the blood is hard to assess. A number of studies suggest that asymptomatic children who have blood lead concentrations in a range of 20 to 40 μg per dl may suffer intellectual and psychosocial impairment. In one study in which school performance and the lead content of deciduous teeth were assessed, a high content of lead was correlated with a decrease in the intelligence quotient of 2 to 4 points, less competence in areas of verbal and auditory processing and decreased attention span.[12] Similar findings have been reported in children living in proximity to lead smelters.[9] Children with higher lead contents were also more likely to have had pica.

Therapy for Lead Poisoning

The therapy for lead poisoning with involvement of the brain and its severity are the critical issues. In patients presenting with encephalopathy such as the first patient, the single most important element of therapy is the removal of lead from brain cells. Before the advent of chelation therapy, children presenting with coma or seizures or both had a mortality rate of 65%. The introduction of treatment with dimercaptol reduced mortality to between 25% and 30%. The substitution of calcium sodium salts of EDTA for dimercaptol did not improve mortality statistics, but the combined use of dimercaptol and EDTA reduced mortality to less than 5%.[13]

Dimercaptol is a dithiol chelating agent that is distributed throughout the body water and enters both the brain and the erythrocytes. It is excreted by both liver and kidney. It reverses the inhibition of the enzymes by heavy metals and provides free sulfhydryl groups. Its toxicity is more disturbing than dangerous. It may produce hypertension, sensation of burning of the lips, nausea and abdominal pain. A problem is that its pharmacologic action lasts only four hours, necessitating intramuscular injections every four hours for optimal results. It is contraindicated in the presence of liver failure and deficiency of glucose-6-phosphate dehydrogenase, where it may produce a hemolytic crisis. It should not be administered along with iron. The dosage is 4 mg per kg of body weight given intramuscularly every four hours for three to five days.

EDTA can be given intravenously or intramuscularly at six-hour intervals. It is not metabolized in the body; 95% is excreted in the urine in 24 hours. It is distributed in 90% of body water, but does not enter erythrocytes and diffuses poorly into brain. In fact, in cases of severe encephalopathy, it may worsen the clinical state and increase hematuria and the plasma concentration of aminolevulinic acid in the first 24 to 48 hours. Toxicity affects the proximal renal tubules. It should be administered only after adequate renal output is assured and never in the presence of anuria or severe renal disease. It may produce hypercalcemia. The dosage of EDTA for children is 75 mg per kg a day divided into four doses given intramuscularly. If given intravenously, it may be given slowly over 3 to 4 hours every 12 hours in a total dose of 50 mg per kg.

EDTA will cause a fall in concentrations of lead in the blood of 20% over the first day of treatment. Treatment with dimercaptol and EDTA combined will cause a fall of 50%,

TABLE 3.—*Effects of Lead Poisoning on the Biosynthesis of Heme**

Normal Pathway	*Intermediate Accumulating in Lead Poisoning*
Succinyl-CoA + glycine	
↓	
δ-ALA	Increased in plasma: Normally less than 0.1 μg/ml, but in lead intoxication, 0.2-1.4 μg/ml; in urine, 0.5 mg/dl or more
Pb → Cytosolic δ-ALA dehydratase	Lead inhibits this enzyme, decreased activity is a very sensitive indicator; found at levels of lead in blood of 10 μg/dl
↓	
Porphobilinogen	
↓	
Uroporphyrinogen III	
↓	
Coproporphyrinogen III	Coproporphyrin III excreted in great excess in urine (signifies current activity)
↓	
Protoporphyrinogen IX	
↓	
Protoporphyrin IX	Accumulates in great excess in erythrocytes and accounts for the fluorescence (this is the basis of the FEP test)
Fe	
Pb	
Mitochondrial ferrochelatase	Lead inhibits this enzyme
↓

*Adapted from Spector and Madden.[4]

along with a pronounced increase in the excretion of lead. This approach also has the advantage of not exacerbating the clinical state initially. Combined therapy is not more toxic. The only problem is the number of intramuscular injections required. In the 8-year-old boy who had ingested *greta* and had a blood level of lead of 93 μg per dl and an FEP of 307 μg per dl, dimercaptol was given intramuscularly and EDTA intravenously. In 24 hours his level of lead was 48 μg per dl; in 96 hours it was 24 μg per dl. In the first 24 hours, his urinary excretion of lead was 25.2 mg, more than half of the total eventually excreted. On the third day 6.9 mg was excreted and on the fifth day 2.1 mg. After two weeks, when the lead burden had reequilibrated, his blood level had reached 55 μg per dl. A second course was administered. This time over the first day he excreted 12.5 mg and on the last day only 0.5 mg. At the time of discharge he was totally asymptomatic and his neurologic state and memory were normal.

The first patient who was comatose and had seizures also had cerebral edema. For this reason, she was given a regimen of mannitol and thiopental sodium in addition to chelation. In our experience, cerebral edema responds well to the administration of mannitol and the removal of lead from the brain cells. It is rarely necessary to be more aggressive. In children who are symptomatic and in those who are asymptomatic but who have a blood concentration of lead greater than 70 μg per dl, we used combined chelation therapy. In the group in whom the level is between 50 and 70 μg per dl, a provocative one-day EDTA test is done to determine the burden of lead. If the amount of lead excreted in the urine is greater than 0.5 mg, a five-day course of EDTA is given. In the group in whom the level is between 30 and 50 μg per dl, removing the child from the source or vice versa may be all that is necessary. All children who are found to be at risk need prolonged careful follow-up. Penicillamine is not a very effective chelating agent for lead and does not have approval from the FDA. It is dangerous to use if a patient is not removed from the source, because it enhances absorption of lead from the intestinal tract.

Questions and Answers

PHYSICIAN IN THE AUDIENCE: *How do you make a diagnosis of lead poisoning?*

DR SPECTOR: The definitive diagnosis is based on the concentration of lead in the blood. The FEP test, which is used for screening for lead poisoning, is also positive in cases of iron deficiency anemia (50 to 250 μg per dl). The most sensitive index of lead effect on heme synthesis is the assay of δ-aminolevulinic acid dehydratase. At blood lead concentrations of 30 μg per dl, its activity is reduced 50%.

PHYSICIAN IN THE AUDIENCE: *What is the significance of lead lines?*

DR SPECTOR: The presence of lead lines in the long bones is an index of a heavy lead burden. This can be determined by the EDTA provocative test. Lead is stored chiefly in bone and it is inactive there.

PHYSICIAN IN THE AUDIENCE: *Is anemia always present in patients with lead poisoning?*

DR SPECTOR: Iron deficiency anemia is not due to lead intoxication although it is often seen as an associated finding. Lead itself does not produce significant anemia but is responsible for the basophilic stippling.

Medical Staff Conference

Na^+-H^+ Exchange, Oncogenes and Growth Regulation in Normal and Tumor Cells

These discussions are selected from the weekly staff conferences in the Department of Medicine, University of California, San Francisco. Taken from transcriptions, they are prepared by Drs Homer A. Boushey, Associate Professor of Medicine, and David G. Warnock, Associate Professor of Medicine, under the direction of Dr Lloyd H. Smith, Jr, Professor of Medicine and formerly Chair of the Department of Medicine. Requests for reprints should be sent to the Department of Medicine, University of California, San Francisco, School of Medicine, San Francisco, CA 94143.

LLOYD H. SMITH, Jr, MD:* *For this Medical Staff Conference, we have a most unusual topic. Dr Harlan Ives is a member of the Nephrology Division at Moffitt Hospital, so we are not surprised to find him speaking on the exchange of sodium and hydrogen ions. It is less common for a nephrologist, or anyone else, to move from that topic to a consideration of oncogenesis and growth regulation. Dr Ives, can you really make that transition? We look forward to hearing a review of the work in that area.*

HARLAN E. IVES, MD, PhD:† In the year 1985 we find ourselves in the midst of a revolution in the understanding of carcinogenesis. Fundamental biologic information on the causes of cancerous transformation of cells that could not have been imagined five years ago is now appearing on an almost daily basis in the various journals of medicine, cell biology, biochemistry, virology and even in general medical texts[1] and the popular literature.[2-4] Perhaps even more significant than the quantity of this new information is the extent to which a limited number of themes appears to recur in work drawn from very diverse sources. This convergence of information has resulted in a remarkable level of enthusiasm about the future of this exceedingly complex and important problem.

In this Conference, I would like to convey this flavor of enthusiasm and review some of the scientific basis for it. In doing so, I will review the oncogene hypothesis and the broad areas of experimental evidence that support it, the relationship between oncogene products and normal growth factors, the biochemical effects that growth factors have on cells and the role of sodium (Na^+)-hydrogen (H^+) ion exchange and cell alkalinization in the regulation of cell growth. Although the topic of this review covers the work of much scientific research over the past five years, understanding only a tiny percentage of this work is needed to realize its profound importance for the study of cancer in the years to come.

*Professor and formerly Chair, Department of Medicine.

†Assistant Professor, Cardiovascular Research Institute and Division of Nephrology, Department of Medicine.

The Oncogene Hypothesis

In its simplest form, the oncogene hypothesis states the following:

Cancer is caused by an abnormal expression of genes found in normal cells. Under normal conditions these genes (more than 20 have been found so far—Table 1) are probably involved in normal cell growth and cellular differentiation.

The oncogene hypothesis embraces older theories of carcinogenesis that were based on years of observation and epidemiologic work. These older theories include as causes viruses, carcinogens, genetic predisposition to cancer and some combination of the above. What was lacking in these older theories was an understanding of how these various etiologic agents conspire to cause cancer. Without this understanding, it was exceedingly difficult to develop rational therapies or preventive measures aimed at the root cause of the disease.

How is the oncogene hypothesis able to explain the earlier observations and unify the older theories of carcinogenesis? First, the oncogene work has shown that viruses can cause cancer by introducing abnormal forms of oncogenes (viral oncogenes) that are similar to their normal cellular counterparts (cellular oncogenes). This mechanism has been shown in many carcinomas found in avian, murine and simian species. Second, mutations in a cellular oncogene have been shown to cause cancerous transformation. Because carcinogens are believed to work by causing mutations in a cell's DNA, it would appear that carcinogens, such as those found in cigarette smoke, cause cancer by creating mutations in specific genes (oncogenes). Third, genetic predisposition to cancer may be due to the presence within a family of an abnormal copy of one of the oncogenes. Members of this family then might be predisposed to a certain type of cancer. Last, the observation that cancer is a slowly progressive process, requiring several causative factors rather than one, may be explained by the observation that, in some cases, cancerous transformation can be caused by only several oncogene abnormalities rather than by only one.

(Ives HE: Na^+-H^+ exchange, oncogenes and growth regulation in normal and tumor cells—Medical Staff Conference, University of California, San Francisco. West J Med 1985 Sep; 143:365-370)

What is meant by "abnormal expression" of a normal gene? When does something that is normal become abnormal? Work on this concept has led to a number of important findings. First, it is not surprising that if a specific gene is damaged by a carcinogen, or if a damaged copy is introduced by a virus, the gene product might behave abnormally. For example, an altered protein might not recognize the intended cell type or it might avoid repression by inhibitory factors. A second type of abnormal expression occurs when there are too many copies of a gene that is otherwise normal in structure. This leads to overproduction of its normal product. This overproduction could cause a loss in the "fine tuning" of growth regulation and lead to cancerous growth. Finally, chromosomal translocations, which occur frequently in certain cancers, such as Burkitt's lymphoma and chronic myelogenous leukemia, have been shown in a number of cases to translocate oncogenes from inactive sites of transcription to active sites. Such an increase in transcription would also lead to overproduction of the protein product of an oncogene. Thus a number of relatively simple mechanisms can be envisioned whereby a normal gene could become abnormal and dangerous to the organism.

Evidence for a Role of Oncogenes in Causing Cancer

The evidence that oncogenes are involved in causing cancer comes from remarkably diverse sources. In Table 2 is summarized the most important of these lines of evidence. In the paragraphs that follow, I will present examples of each.

The earliest evidence for the oncogene hypothesis was obtained in the study of viruses that cause cancer in birds and rodents. Although most of these viruses do not appear to be involved in human cancer, the oncogene concept ties virally induced cancers together with nonvirally induced cancers in a clear and convincing way. First, transforming retroviruses (these are viruses that contain RNA, can transcribe it into DNA via the enzyme reverse transcriptase and that cause cancer in birds and rodents) often contain oncogenes. As early as 1911, Rous found a filterable agent that could cause sarcoma in chickens.[5] He believed this agent to be a virus, but because it was firmly believed at the time that cancer is not an infectious process, but rather that it arises de novo in each case, Rous's viral hypothesis was ridiculed for many years. By the 1930s and 1940s, however, it was becoming increasingly clear that not only did the Rous virus cause sarcoma in chickens but other viruses were being found that caused cancers in other species. These discoveries ultimately led, in 1965, to a Nobel prize for Rous, 54 years after his initial work. Yet, even at this late date, the entire significance of Rous's finding was not yet fully appreciated. In 1976 a startling discovery was made in the laboratory of Varmus and Bishop at the University of California, San Francisco. They found that the *src* gene (without which Rous virus does not cause sarcoma in chickens) is actually similar to a gene found in all normal chickens[6] and other higher organisms including humans.[7] Thus, the *src* gene appears to be highly conserved across eons of evolutionary time and is not simply a curiosity of chicken sarcoma. Rather, *src* is a biologic entity of considerable general importance. Since this discovery, more than 20 such retroviral genes have been found that are similar to normal vertebrate and human genes (Table 1). These genes are now referred to as the viral oncogenes, and their animal counterparts are referred to as cellular oncogenes.

The second line of evidence that viral oncogenes are involved in causing cancer is almost an aside to the first. Several retroviruses that cause cancer do not contain oncogenes. However, some of these were subsequently found to uniformly insert viral DNA into a cellular oncogene following viral infection. This phenomenon is called insertional mutagenesis because it mimics mutation through insertion of viral genetic material into oncogenes.[8]

The third line of evidence that oncogenes are involved in cancer actually derives from work with a human cancer—a neoplasm of the urinary bladder. It has long been known that DNA derived from cancer cells, when incubated with normal cells in such a way as to allow uptake of the DNA, can frequently cause transformation of the cells into malignant cells. With modern sequencing and cloning techniques, it was possible to identify the precise DNA sequences that were responsible for this transformation. A "transforming principle" was purified that was 50,000 times more potent than whole cell DNA in causing cell transformation. This DNA

TABLE 2.—*Major Lines of Evidence That Link Oncogenes to Carcinogenesis*

Transforming retroviruses frequently contain genetic material homologous to the oncogenes
Other transforming retroviruses are capable of inserting viral sequences into a cell's oncogenes
Sequences of tumor cell DNA homologous to oncogenes will transform certain normal cells
Many tumor cells overproduce the protein products of oncogenes
Chromosomal translocations in tumor cells contain oncogenes

turned out to be homologous to one of the viral oncogenes, *ras*. Of perhaps even greater interest, *ras* derived from urinary bladder carcinoma differed from normal *ras* by a single amino acid.[9,10] In other words, a point mutation of an oncogene could transform a normal, benign constituent of the cell to a cancer-causing agent.

Human cancers have now also been shown to overproduce the protein products of oncogenes. Human osteosarcoma cells[11] and human glioma cells[12] both secrete large amounts of a protein with significant homology to the product of the oncogene *sis*. The *sis* gene was originally identified as the gene that enables the simian sarcoma virus to cause sarcoma in monkeys. The protein product of this gene was identified and looked for in various human tumors. Indeed, the cells described produce large quantities of this material, again providing powerful suggestive evidence for a role of oncogenes in causing human cancers.

Finally, evidence for an involvement of oncogenes in human cancer has been arrived at by careful analysis of chromosomal translocations in certain human cancer cells. The best known of these is the Philadelphia chromosome, in which part of the short arm of chromosome 22 is exchanged for a fragment of the long arm of chromosome 9. The abnormality has been known to cytologists and oncologists for many years[13] as a marker for chronic myelogenous leukemia for which it has very high specificity and more than 85% sensitivity. With the development of more sophisticated genetic methods, it has become possible to determine specifically which genes are involved in this transfer of DNA. In 1983 it was discovered[14] that the fragment of chromosome 22 involved in the transfer contains the *sis* oncogene and the fragment of chromosome 9 contains the *abl* oncogene (Figure 1). While it is still not known what role this gene transfer has in transforming bone marrow cells to malignant cells, this finding provides provocative evidence for a role of oncogenes in causing chronic myelogenous leukemia.

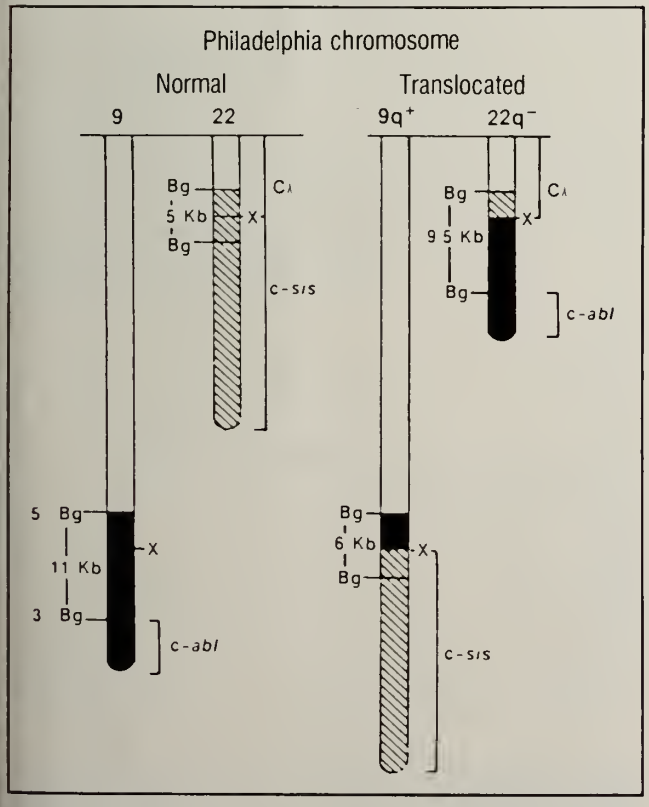

Figure 1.—The fragments of DNA that are exchanged in the Philadelphia chromosome each contain oncogenes (from Heisterkamp et al[14]).

More convincing is the recent finding[15] that chromosomal translocations in Burkitt's lymphoma result in the transfer of the *myc* oncogene from chromosome 8 to the region of chromosome 14 that carries the immunoglobulin heavy chain. This translocation results in the placement of the *myc* gene under new control. Because heavy chains are synthesized in large numbers in these B cells, *myc* synthesis is greatly increased.[16] Although the mechanism by which *myc* transforms the lymphocyte is not yet known, the increase in *myc* product synthesis appears almost certainly to be a crucial factor in this transformation.

The Role of Oncogenes in Normal Cells

If the oncogenes are indeed "normal" genes until they become modified by viruses or carcinogens, then what is their role in normal cells? An answer to this question has begun to emerge from work in many laboratories over the past five years. It appears that some of the oncogene products are involved in the control of normal cell growth and differentiation (for review, see Bishop[8] and Heldin and Westermark[17]). Only when the control of their expression is subverted do they develop the potential to cause cancer. The first hard piece of evidence that this was the case came in 1980. Recall that in 1976, Stehelin and co-workers[7] showed that one of the oncogenes (*src*) was similar to a normal cellular gene. In 1980 it was found that the product for *src* has a most unusual enzymatic activity. The *src* product is a protein kinase that phosphorylates proteins on tyrosine residues.[18] Protein kinases are not at all unusual, but less than 0.1% of the protein-bound phosphate is found on tyrosine residues and no enzyme had previously been described that carried out this phosphorylation. The correlation to growth factors came with a most surprising report from Ushiro and Cohen at Vanderbilt University (Nashville, Tenn).[19] The purified receptor for epidermal growth factor also shows tyrosine-specific protein kinase activity.[19] Subsequently, this enzyme has been found in association with many of the other oncogenes and with the receptors for insulin and platelet-derived growth factor.

More direct evidence for a relationship between oncogenes and normal growth regulation comes from work with cellular growth factors. For many years it has been known that eukaryotic cells do not grow in culture without one of several growth factors found normally in serum. Examples of such growth factors include epidermal, nerve and platelet-derived growth factors and hormones like insulin and vasopressin. In an intact organism, platelet-derived growth factor is responsible for proliferation of cells in the vascular intima after damage. In 1983 Waterfield, Deuel and their collaborators made a remarkable series of discoveries. The oncogene of simian sarcoma virus, *sis*, codes for a protein with a high degree of homology to platelet-derived growth factor[20] and stimulates cells through receptors for the growth factor.[21] Subsequently, Downward and associates, working with Waterfield, found that the product of another oncogene, *erb-B*, has homology with the receptor for epidermal growth fac-

tor.[22] Thus, these oncogene products appear to transform cells through abnormal production of normal growth factors or their receptors. Normally, the production of these proteins is probably only transient, when cell proliferation is required. Cell transformation occurs when growth factor production becomes unregulated.

What Are the Biochemical Effects of Growth Factors on Cells?

Upon binding of a growth factor to a cell surface, a number of significant biochemical events occurs within minutes to hours. The most important of these are summarized in Table 3. Two enzymatic activities appear uniformly to be stimulated upon binding of growth factors. First is the activity associated with the *src* gene, tyrosine-specific protein kinase. As discussed above, tyrosine phosphate is a very rare component of cell protein. Thus, tyrosine-specific protein kinase must work on only a very small number of specific proteins. Thus far, several membrane proteins have been identified that are phosphorylated on tyrosine residues, including the kinase itself, but, other than the kinase activity, the function of these proteins is not known.

A second important biochemical activity stimulated by growth factors is inositol phospholipid turnover. Until recently, inositol phospholipids were thought to be merely a curious minor component of cell membranes. However, it has now become apparent that many growth factors cause enzymatic degradation of inositol phospholipids to inositol trisphosphate and the glycerol backbone, diacylglycerol (for review, see Berridge and Fine).[23] These two breakdown products of inositol phospholipids are probably both intracellular messengers. Inositol trisphosphate appears to have an important role in the mobilization of intracellular calcium (Ca^{++}), and diacylglycerol stimulates the enzyme "kinase C," a calcium- and phospholipid-sensitive protein kinase that phosphorylates a number of proteins on serine or threonine residues.

Third, the interaction of growth factors with cells often causes expression of oncogene products located in the cell nucleus, like *myc* and *fos*. This phenomenon appears to tie together those oncogene products that are similar to growth factors or their receptors with a second set of oncogenes that are expressed after stimulation by growth factors.

The fourth major response of cells to growth factors is an increase in intracellular Ca^{++}. This response does not appear to be specific for growth but rather accompanies hormonal activation of many types.

Last, binding of growth factors to cells causes a rapid increase in intracellular pH from a resting value of about 7.0 to 7.2. Although this increase seems to be small, Daniel and myself (Figure 2) and others[24,25] have had no difficulty in detecting it with modern methods (T. O. Daniel, MD, and H. E. Ives, MD, PhD, unpublished observations, February 1985) and it is certainly large enough to cause profound changes in several important cellular functions.

Growth Factors Cause Intracellular Alkalinization

The idea that cell pH changes might somehow be involved in the process of cell division has been entertained for many years. In fact, as early as 1913, Loeb showed that exposure of sea urchin eggs to ammonium hydroxide could initiate a process of artificial fertilization such that the egg would begin to mature in the absence of sperm.[26] Progress on this provocative idea was not made for the next 60 years because of the difficulty of making accurate cell pH measurements. Not until 1976 did Johnson and associates finally prove convincingly that a 0.3 unit pH change accompanies sea urchin egg fertilization.[27] More important, if this pH change is blocked by low Na^+ or amiloride (an inhibitor of the Na^+-H^+ exchanger), the changes of fertilization do not occur.

What is the relevance of sea urchin eggs to our discussion of growth regulation and transformation in mammalian cells? It now appears that many mammalian cells undergo a similar cell alkalinization as an early response to the presence of growth factors or agents that can cause cancerous transformation of cells. Table 4 provides a partial list of agents that have so far been shown to cause intracellular alkalinization. One of these is platelet-derived growth factor, the protein with significant homology to the transforming protein of the simian

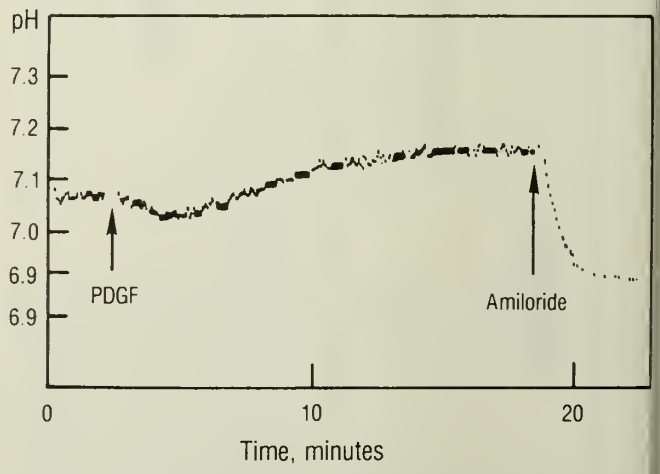

Figure 2.—Measurement of intracellular pH in 3T3 fibroblasts after addition of platelet-derived growth factor (PDGF) and an inhibitor of the sodium-hydrogen ion exchanger, amiloride. pH was monitored with an intracellular trapped fluorescent dye, (2′-7′)-bis(carboxyethyl-[5,6]-carboxyfluorescein).

sarcoma virus, and a protein that is produced in tremendous quantity by human osteosarcoma and glioma cells. It is also of interest that epidermal growth factor, whose receptor is coded for by the oncogene *erb-B*, also causes intracellular alkalinization. How and why do these growth factors and oncogene products cause alkalinization?

How Do Growth Factors Cause Intracellular Alkalinization?

The answer to this question of how growth factors cause intracellular alkalinization requires some knowledge of how cells regulate their pH under ordinary circumstances. Because of the interior negative membrane potential found in most cells, and because of metabolic acid production, cells must constantly extrude H^+ to maintain the normal intracellular pH of 7.0 to 7.2. The mechanism for intracellular pH regulation in higher organisms (in bicarbonate-free medium) is Na^+-H^+ exchange. In bicarbonate-containing media, an additional pH regulatory system has been found in some cells. However, this latter system is beyond the scope of this review. Na^+-H^+ exchange harnesses the energy present in the Na^+ gradient (formed by action of the sodium-potassium adenosine triphosphatase [Figure 3]) to drive H^+ out of the cell. Because Na^+-H^+ exchange never reaches thermodynamic equilibrium, it is possible for a cell to alter its pH by changing the rate at which Na^+-H^+ exchange is operating. Thus, if Na^+-H^+ exchanger activity were increased, the cell pH would rise, and if Na^+-H^+ exchange activity decreased, cell pH would decrease.

Current evidence indicates that this is precisely how growth factors cause an increase in intracellular pH. This evidence can be summarized as follows:

- Alkalinization caused by growth factors is accompanied by Na^+ entry.[24,25,28]
- Alkalinization is blocked by the removal of Na^+ from the medium.[25,28]
- Alkalinization and Na^+ entry are both blocked by the diuretic drug amiloride,[25,28,29] which is known to inhibit the Na^+-H^+ exchanger in isolated membrane systems.[30,31]

Why Do Growth Factors Cause Intracellular Alkalinization?

The answer to the important question of why growth factors cause intracellular alkalinization is not yet completely known. However, work from the laboratory of Pouysségur and co-workers in Nice is beginning to unravel the mystery.[29,32] They cleverly obtained mutants of fibroblasts that lack Na^+-H^+ exchangers. These mutants grow normally at alkaline pH but cannot maintain growth if the pH of the medium is reduced below 7.2. (Wild type cells grow, albeit slowly, even when the pH is reduced to 6.5.) Pouysségur and associates looked at the intracellular pH of both types of cells as extracellular pH was lowered. Wild type cells tend to maintain their intracellular pH near 7.2 even as the medium is reduced below pH 7.0. Cell pH in the mutants could not be maintained as medium pH was lowered. When they looked at the dependence of DNA synthesis on intracellular pH in these cells, they found that DNA synthesis is shut off precisely at pH 7.2 in both types of cell. Thus, it appears that the reason the mutants cannot grow in acid medium is because they cannot maintain their intracellular pH above 7.2 in acid

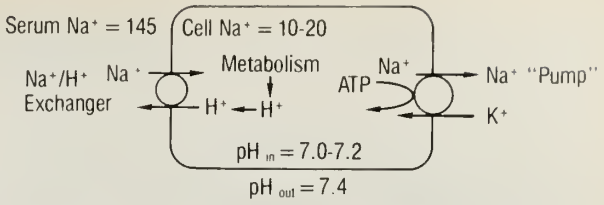

Figure 3.—The cell maintains its intracellular pH by extrusion of hydrogen ion (H^+) in exchange for entrance of sodium ion (Na^+) into the cell. The energy for this transport process comes from the low cell Na^+ that in turn is generated by action of the Na^+-potassium (K^+) adenosine triphosphatase (ATPase).

growth media. Finally, in a separate work,[32] Pouysségur and colleagues showed that amiloride analogues block DNA synthesis in wild type cells with the same order of potency that they block Na^+-H^+ exchange in these cells. Thus, it appears that Na^+-H^+ exchange is necessary for the maintenance of the correct cell pH for DNA synthesis and cell division to occur. Growth factors and certain oncogene products stimulate Na^+-H^+ exchange and thus provide the proper intracellular environment for cell division of cancerous transformation.

These remarkable new findings that I have discussed here seem to provide a firm basis for the understanding of the cause of many, if not all, types of cancer. Thus far these new laboratory findings have not yielded new approaches in the treatment of cancer, but it seems only logical that these will be forthcoming. On this problem, Bishop has said, "Will we be able to parlay the growing information about oncogenes into devices for the prevention, diagnosis and treatment of human cancer? It is too early to foretell how quickly the answer to this question might come, but there now seems little reason to doubt that we have laid hold of cancer with a grip that should eventually extract the deadly secrets of the disease."[1]

Summary

Cancerous transformation of cells is caused by the altered expression of one or more of a small group of genes known as "oncogenes." This altered expression can be due to a mutation of the gene or to a derangement in the rate of production of the product of an otherwise normal gene. Under normal conditions, these genes are almost certainly involved in normal cellular growth and differentiation. In several cases, oncogene products appear to be closely related to growth factors found in normal serum. These growth factors are known to cause a number of biochemical alterations within cells. One of these alterations is intracellular alkalinization, stimulated by increased activity of the Na^+-H^+ exchanger. This alkalinization appears to be necessary for the initiation of DNA synthesis.

Epitomes
Important Advances in Clinical Medicine

Radiology

The Scientific Board of the California Medical Association presents the following inventory of items of progress in radiology. Each item, in the judgment of a panel of knowledgeable physicians, has recently become reasonably firmly established, both as to scientific fact and important clinical significance. The items are presented in simple epitome and an authoritative reference, both to the item itself and to the subject as a whole, is generally given for those who may be unfamiliar with a particular item. The purpose is to assist busy practitioners, students, research workers or scholars to stay abreast of these items of progress in radiology that have recently achieved a substantial degree of authoritative acceptance, whether in their own field of special interest or another.

The items of progress listed below were selected by the Advisory Panel to the Section on Radiology of the California Medical Association and the summaries were prepared under its direction.

Positron-Emission Tomography of the Heart

MYOCARDIAL PERFORMANCE is determined by complex biochemical processes that modulate contractility, electrophysiologic events and cell viability. In vivo assessment of myocardial metabolism has been difficult to accomplish in the past. Until recently, nuclear cardiologists focused on functional imaging such as the evaluation of myocardial blood flow using thallous chloride Tl 201 and the study of ventricular function by radionuclide ventriculography. With the recent advent of positron-emission tomography (PET), however, the field of nuclear cardiology enters a new era by imaging regional metabolic processes. This tomographic, three-dimensional approach provides quantitative determination of myocardial tracer distribution because photon attenuation can be accurately corrected for. Positron-emitting isotopes such as fluorine 18, oxygen 15, carbon 11 and nitrogen 13 can be used to label physiologically occurring substrates for the in vivo study of myocardial cell function. The current generation of the PET cameras with high spatial (5 to 10 mm) and dynamic resolution (three to ten seconds per image) provide accurate quantitation of myocardial perfusion and metabolism using validated tracer kinetic models. These characteristics make positron-emission tomography a unique tool for the in vivo assay of biochemistry, which links structure and function in a living organism.

In studying the heart, PET has been used mainly in patients with ischemic heart disease and cardiomyopathy. Regional myocardial blood flow is being evaluated using rubidium chloride Rb 82, ammonia N 13 and water O 15, whereas myocardial substrate metabolism is studied using carbon palmitate C 11 as a tracer for fatty acids and fluorine deoxyglucose F 18 (FDG) as an analog for glucose. Using PET, studies in animals and clinical studies have shown that normal myocardium is characterized by a close match of flow and substrate metabolism because both reflect regional energy demand. The same is true for infarcted myocardium where flow and metabolism are low due to the low perfusion and energy requirements of scar tissue. During ischemia, myocardium cannot oxidize fatty acids but uses glucose anaerobically to meet its basic energy requirements. This regional shift in myocardial metabolism during ischemia can be detected noninvasively by PET as shown in experimental and clinical studies. Therefore, ischemic but viable tissue can be detected noninvasively. Using metabolic tissue characterization, studies of animals showed that PET can predict recovery of function following transient ischemia. Encouraged by these results, PET has been applied to patients with acute myocardial infarction. In a considerable number of patients, viable but compromised tissue was observed in "electrocardiographically infarcted" segments of the left ventricle. The metabolic definition of viable but compromised myocardium early during evolving infarction is most important for salvaging myocardium in view of therapeutic interventions such as thrombolysis and angioplasty. Additionally, in patients with severe coronary artery disease and impaired left ventricular function, PET images have been shown to be predictive for the success of a coronary artery bypass procedure. Myocardium with impaired flow but maintained glucose metabolism as estimated by FDG uptake showed functional recovery, while segments with low flow and low metabolism did not recover postoperatively. Because patients with impaired ventricular function have a higher surgical risk, carefully selecting patients for a surgical procedure is clinically important.

In cases of dilated cardiomyopathy, heterogeneous free fatty acid metabolism has been shown by a patchy uptake pattern of carbon palmitate C 11. Furthermore, in patients with severe left ventricular dysfunction, the response of fatty acid metabolism to glucose loading was substantially abnormal. To improve our understanding of the pathophysi-

ology of cardiomyopathy, further research in this area will focus on detecting biochemical defects before deterioration of function occurs. Finally, in patients with Duchenne's muscular dystrophy, there is evidence of a localized myocardial metabolic abnormality that is unique to this disease and can be detected by PET. Again, FDG proved to be a sensitive marker of a regional shift in substrate metabolism.

Positron-emission tomography is still in its infancy, but these initial studies show the potential for metabolic imaging in cardiac disease, especially for such important clinical questions as defining tissue viability in patients with ischemic heart disease. Refining the technique will allow more accurate diagnosis of cardiac disease and better biochemical understanding of the underlying cause.

New Developments in Contrast Media

RESEARCH OF CONTRAST MATERIAL has recently brought into focus a number of new developments that should have major impacts on the practice of radiology in the near future.

The first of these is the production and clinical testing of low-osmolality media. In general, these new substances take one of two forms: nonionic agents or monoacid dimeric agents. These substances differ from the current ionic media by a decrease in the osmotic pressure of the molecules for a given concentration of iodine. Thus, the new media have a ratio of iodine atom to dissolved particle of 3, whereas current media have a ratio of 1.5. Animal and clinical testing to date indicate that the low-osmolality media are both safer and more comfortable when used for arteriography. While the chemotoxicity of these media is substantially less than that of current media, the data on anaphylactoid effects are still incomplete. Preliminary findings, however, suggest that a significant improvement can be expected in this area also. Currently, only one nonionic agent (metrizamide) is approved for intravascular use in this country. Other nonionic agents are pending approval by the Food and Drug Administration and, when available, will probably become the agents of choice for arteriography. Because they are expected to be considerably more expensive than current ionic media, their overall role in vascular injections remains to be determined. Results of both studies on animals and clinical studies suggest that these media will also confer less toxicity in the subarachnoid space than metrizamide or iophendylate (Pantopaque).

The second development of note concerns the use of perfluorocarbons as contrast agents for ultrasonography. Nonbrominated perfluorocarbons are presently used in humans as oxygen-carrying blood expanders and these substances, when injected as emulsions in both the brominated and nonbrominated forms, appear to combine a low toxicity with effective uptake by reticuloendothelial cells and macrophages, resulting in increased echogenicity of the liver and spleen and experimentally induced tumor rims and myocardial infarcts. Preliminary trials in humans are currently under way and appear highly promising, particularly for enhanced visualization of liver tumors.

The third area of particular interest is the development of contrast agents for magnetic resonance (MR) imaging. Preliminary observations suggest that such agents will dramatically extend the diagnostic value of MR imaging, despite the inherent high-contrast differences obtainable for different tissues with this new technique. Conventional radiographic contrast media produce their effect by high-electron density that absorbs x-rays. MR imaging media, as currently conceived, function by altering local magnetic environments. These paramagnetic substances can be used for intravascular injection, subarachnoid installation or gastrointestinal tract opacification. Data on animals and preliminary data on humans suggest that these compounds can be used effectively in a fashion similar to that of conventional media with very low toxicity anticipated.

Each of these new developments should reach a stage of clinical use within one to three years, with the advent of the new nonionic media for conventional radiography expected within a year.

Computed Tomography of the Spine

BECAUSE OF ITS ABILITY to show both soft tissue and bone abnormalities in excellent detail, high-resolution computed tomography (CT) has assumed a dominant role in imaging of the spine, particularly in the lumbar area. Its efficacy in evaluating degenerative disc disease, tumor, trauma, congenital abnormalities and infectious processes has been documented.

More than 95% of lumbar disc herniations occur between L-3 and S-1, so that by scanning these three levels most lumbar disc problems will be encompassed. Contiguous 4- to 5-mm thick axial scans are taken, with additional scans parallel to the discs obtained in some cases. Contiguous scans decrease the likelihood of missing herniated disc fragments that have migrated above or below the disc level and, in addition, make possible sagittal and coronal reformations that are useful in some cases. CT is more accurate than conventional myelography in diagnosing lumbar disc herniation because even lateral and L5-S1 herniations remote from the thecal sac can be readily seen. CT clearly shows central and foraminal spinal stenosis that often plays a significant role in low back syndromes. Abnormalities of the facet joints, which may contribute to low back pain, are also clearly shown. By showing whether root compression is due to focal herniation or bulging of the annulus and whether there is extruded disc material, selection of appropriate therapy such as surgical repair or enzyme injection can be aided. Evaluating the lumbar spine postoperatively with plain CT may be difficult because of surgical distortion. The use of intravenous contrast media in this situation can help distinguish between recurrent disc herniation and scarring.

The role of plain CT in evaluating cervical disc disease is more controversial. Although thin-section CT (1.5- to 2-mm slices) can demonstrate disc herniations and spondylotic changes, diagnostic accuracy is not as high as in the lumbosacral spine. Many authors advise using an intrathecal water-soluble contrast agent to improve the diagnostic accuracy of CT examination of a patient with cervical degenerative disc disease.

The major limitation of plain CT is its inability to show intradural pathologic processes such as tumors. Conventional myelography or CT with intrathecal water-soluble contrast material is indicated when an intradural abnormality is suspected.

Radiation Risks in Diagnostic Radiology

THE RISKS OF HARMFUL GENETIC and somatic effects associated with the low doses (a few rads or less) of ionizing radiation received during diagnostic x-ray examinations are too small to be measured. The existence of deleterious effects from much higher doses is irrefutable. The major uncertainty in inferring low-dose risks from dose-effect data obtained at high doses is selecting the type of extrapolation to be used in continuing the dose-effect curve into the low-dose region. Estimates obtained from a no-threshold, straight-line extrapolation of high-dose dose-effect data in animals and, in some instances, humans, to low doses, will be used here. Such estimates are generally considered "worst case," in that alternative plausible extrapolation schemes lead to lower estimates of risk at low doses.

The genetic risk resides in radiation-induced mutations, generally considered deleterious, which can be passed on to future generations via reproduction. No deleterious genetic (or somatic) effect has ever been documented from natural background radiation. This suggests that if the genetically significant dose, estimated in 1970 to be 0.02 rad per capita per year, remains well below the background radiation dose of 0.1 rad per capita per year at sea level, any additional genetic consequences will neither differ in kind nor exceed in quantity those that have been experienced throughout human history. To obtain a numerical estimate is futile, but taking into account that the dose required to double the spontaneous mutation rate is generally assumed to be 20 to 200 rads, the genetic risk of ionizing radiation from diagnostic x-ray studies would appear to be small. Even so, prudence dictates the maximum possible reduction of human gonadal exposure from diagnostic x-ray studies. To this end, gonadal shielding should be used whenever possible during x-ray procedures on a potentially procreative person.

No direct evidence exists for an association between radiation exposure in utero and harm to an unborn child as a result of a diagnostic x-ray study of the lower abdomen or pelvis of a pregnant woman. However, indirect evidence suggests the possibility of radiogenic birth defects and childhood leukemia. The estimated hypothetical risk of an observable birth defect from a 1-rad in utero dose is 1 to 5 chances in 1,000, whereas the natural incidence rate of birth defects is 40 to 50 per 1,000 live births. Studies in animals indicate that the most critical period for inducing a deformity is during organogenesis, weeks 3 through 7 postconception in humans. Human in utero exposure at high doses from the atomic bomb explosions at Hiroshima and Nagasaki indicates weeks 8 through 15 postconception to be the most critical period for inducing mental retardation. Although not seen in these persons, an increased chance of childhood leukemia for an in utero dose of 1 to 2 rads, from a spontaneous incidence rate of 1 per 3,000 to 1 per 2,000, is suggested by some retrospective epidemiologic studies. These possible risks should be explained to a pregnant patient and documented in her record.

The major concern regarding postnatal exposure to diagnostic x-ray studies is carcinogenesis. The estimated hypothetical lifetime risk per study of cancer developing after a latent period of 10 to 25 years varies from a few chances in a million for a (0.05-rad) two-view chest examination to almost 100 chances in a million for a (3-rad) computed tomographic brain scan. These risks are modest compared with the lifetime risk of dying in an auto accident—1 in 100—or contracting cancer spontaneously—180 in 1,000. The most recent screen-film systems for mammography deliver a mean glandular tissue dose as low as 0.1 rad for a two-breast, two-view study, giving an estimated lifetime risk per study for breast cancer induction after a latent period of 10 to 25 years in a woman aged 40 years or older of no more than a few chances in a million, compared with a natural risk of 1 in 10. The hypothetical risk is down dramatically from a decade ago as a result of the great reduction in dose which fact supports routine screening by age 40 as suggested by the American College of Radiology and the American Cancer Society.

In conclusion, the risks from diagnostic x-ray studies are too small to be measured directly. Estimates of the hypothetical risks show them to be small compared with many risks encountered in day-to-day life in American society. Nonetheless, diagnostic x-radiation must be used prudently and every attempt made to obtain the desired diagnostic information with the minimum radiation dose.

Neonatal Intracranial Ultrasonography

ULTRASONOGRAPHY OF THE NEONATAL BRAIN is a quick, noninvasive procedure that can be done on fragile neonates in an intensive care nursery without sedation. High-frequency sector-image ultrasound is used to examine the brain through open fontanelles and sutures.

Ultrasonography is most important for diagnosing intracranial hemorrhage due to the combination of immaturity of the germinal matrix that lines the ventricles and immaturity of the lungs and the autoregulatory system. This bleeding is the

most common central nervous system (CNS) disorder in premature infants younger than 32 weeks' gestation, occurring in 40% to 60% of such children. Ultrasonography can show subependymal, intraventricular or intracerebral germinal matrix hemorrhage in the acute or the convalescent phase.

Serial examinations are helpful for evaluating the progression of hemorrhage, the development and course of posthemorrhagic hydrocephalus and, in some cases, the development of periventricular leukomalacia or porencephaly. Ultrasonography of periventricular leukomalacia is now considered more accurate and reliable than computed tomography (CT).

Ultrasonography can be helpful in diagnosing CNS malformations such as congenital hydrocephalus, holoprosencephaly, agenesis of the corpus callosum, hydranencephaly, Dandy-Walker cysts, intracerebral tumors and arteriovenous malformations. CT, angiography or both may be necessary for further characterization.

Ultrasonography is also useful in evaluating term neonatal asphyxia, intrauterine and postnatal CNS infections, head trauma and hemorrhage due to coagulopathy, but CT is usually more definitive in such cases. Cerebellar and subarachnoid hemorrhage is difficult to image with ultrasonography because the cerebellum, the subarachnoid space and clotted blood are all echogenic.

Because the anterior fontanelle is the primary window used to examine the brain, a small fontanelle or overlapping skull bones will limit the quality of the examination. Also, the convexities of the cerebral spaces are not adequately visualized from the anterior fontanelle and, therefore, CT is preferable for examining these areas. Subcutaneous emphysema will also limit or preclude ultrasonography of the brain.

Ultrasonography has proved useful for diagnosing and following various neonatal brain disorders. And it can be used on infants whose condition is too unstable for them to be examined by other methods.

Percutaneous Removal of Renal and Ureteral Stones

PERCUTANEOUS REMOVAL of symptomatic renal and ureteral calculi is now a routine radiologic method that has replaced open stone operations in the vast majority of patients. Not only simple renal pelvic stones but also calyceal, ureteral and staghorn calculi can be managed successfully percutaneously.

Assessing a patient's blood coagulating properties and obtaining informed consent are part of the routine preprocedure workup. Pretreating with antibiotics is important in patients with a history or symptoms of urinary tract infection. Carefully evaluating the patient's renal anatomy based on previously taken intravenous urograms is essential for planning the optimal access route. We do dilations up to 24 or larger French sizes as a single-step procedure using epidural anesthesia. With the aid of fluoroscopy or endoscopy, stones are removed using baskets, grasping forceps or by ultrasonic lithotripsy. A nephrostomy tube is left in the renal pelvis for at least 24 to 48 hours. It is removed when residual stone fragments have been excluded and good antegrade flow of urine has been confirmed. Hospital stays range from three to seven days in uncomplicated cases, but may be as long as two to three weeks in patients with staghorn calculi or many calyceal stones. Close cooperation between the radiologist and urologist has proved helpful for optimal patient management.

The success rate for percutaneous removal of kidney stones is 95% and for removal of ureteral stones it is about 90%. Occasional stone fragments left behind are usually small and asymptomatic.

Major complications occur in less than 5% of patients. They include hemorrhage, which is usually well controlled by blood transfusions and balloon tamponade and rarely requires angiographic embolization. A surgical procedure and nephrectomy are extremely rare complications. Urosepsis occurs in less than 1% of patients and responds readily to antibiotic treatment, provided there is good urinary drainage.

The advantages of percutaneous stone removal over surgical nephrolithotomy or ureterolithotomy are lower morbidity, shorter hospital stay, shorter recovery period and reduced cost.

A new technique for renal stone removal is extracorporeal shock wave lithotripsy. This is a noninvasive method that uses focused ultrasound waves to fragment stones. Its overall success rate approaches 90%. Percutaneous nephrostomy with tract dilatation is the method of choice in the other 10% of patients. Furthermore, percutaneous or retrograde manipulations of the genitourinary tract are required in 8% or 9% of patients who are treated with this technique to relieve ureteral obstruction resulting from passing stone fragments.

Ultrasonography in the Operating Room

RECENT TECHNICAL ADVANCES in instrumentation have led to diverse and innovative applications of ultrasonography including its use in the operating room. High-resolution real-time ultrasound units that are portable with scan heads that are relatively small and easily maneuvered have greatly increased the number of uses of sonography in the operating room. The ultrasound probes are placed directly onto the operative field after the probe is enclosed in sterile coverings. In this way, real-time imaging of the operative site provides a surgeon with immediate information before, during or after the operation.

One of the original and now well-established uses of intraoperative ultrasound is in the neurosurgical suite. There are three main applications of intraoperative ultrasonography in neurosurgery: guiding a shunt tube placement, brain biopsy and spinal cord operations. Sonographic monitoring of shunt tube placement allows correct positioning and alleviates pos-

sible complications associated with tube placement. Ultrasonography can guide a neurosurgeon in locating a tumor for possible resection and it may be used to evaluate the adequacy of resection after the procedure. In cases in which either an intracerebral or an intraspinal biopsy without resection is necessitated, specialized biopsy guide attachments may be used to allow visualization of the biopsy needle as it is passed into a lesion. Closed brain biopsy improves the rate of tissue recovery and decreases the time of operation. Recently, intraoperative ultrasonography has also been helpful in monitoring the reduction of spinal fractures.

Neurosurgical applications of high resolution intraoperative ultrasonography have been adapted recently for other areas of the body. The development of small high-resolution probes allows their use within the abdomen. The use of ultrasonography to examine the biliary tract and pancreas during a surgical procedure has received the greatest attention. Some of these applications include assessing the gallbladder and biliary system for calculi, locating the common bile duct during difficult explorations, assessing the extent of pancreatitis and detecting and evaluating pancreatic neoplasms. When renal stone resection is required, ultrasonography may be used for guidance. It will show the site of renal calculi and aid a surgeon in avoiding vital structures such as renal arteries and veins during dissection. Sonography has been helpful in detecting intra-abdominal abscesses or in guidance for resection of intra-abdominal tumors. Precision in localization in the abdomen with ultrasound has dramatically reduced the need for extensive surgical exploration, thus avoiding possible complications in critical areas, and it is helpful in assessing the adequacy of a surgical procedure.

Another possible application of intraoperative ultrasonography is in vascular operations to precisely locate pathology before a vessel is open and to check for vascular defects after reconstruction is completed. Ultrasonography can be used in small vessels including during intraoperative assessment of aortocoronary bypass grafts. There are a large number of current and future applications of intraoperative ultrasonography. The acceptance of a particular use will depend on the practical value of ultrasound to reduce operating room time, increase operative safety and ensure the success and efficiency of surgical procedures by improving diagnosis and localization.

Mammography—Its Use and Risks

MODERN MAMMOGRAPHY is the most accurate method known for evaluating the breasts. It is capable of detecting breast cancer at an earlier, highly curable stage.

Mammography is indicated in a woman who has a breast mass, pain or nipple discharge. It is useful not only in evaluating the site of clinical abnormality but also in surveying the opposite breast. In patients with metastatic disease of unknown origin, mammography is indicated in the search for a primary lesion.

Mammography is the only examination regularly capable of detecting "minimal cancers," those that are in situ or infiltrating but less than 5 mm in diameter. It is the only imaging method currently acceptable for screening asymptomatic women. The American Cancer Society recommends that every woman have a baseline mammogram between the ages of 35 and 40. Subsequent examinations should be obtained every one to two years, depending on risk factors. At age 50 and older, yearly mammography is recommended.

Although mammography represents the "gold standard" in breast imaging, its limitations should be recognized. First, the accuracy of mammography is limited in women with radiographically dense breasts. A false-negative rate as high as 10% may occur in cases of clinically palpable carcinoma, particularly when the breasts are very dense. If there are clinically suspicious palpable findings, then the lack of specific findings on mammography should not preclude further investigation, including needle aspiration or biopsy. Second, mammography does not always give a specific diagnosis—that is, it may detect a mass but additional procedures, such as ultrasonography to determine if the mass is solid or cystic, and aspiration or biopsy may be necessary to determine whether the mass is benign or malignant. Third, because the breasts of women in their teens and twenties tend to be dense, and because the breast parenchyma is felt to be more sensitive to the effects of irradiation in these patients, mammography should be restricted to cases in which there is a high clinical index of suspicion of malignancy. If there are clinically palpable masses in young women, ultrasound should be considered for the initial examination. If an ultrasonogram does not adequately answer the clinical questions, then mammography should be used.

The radiation doses in mammography are quite low, particularly the doses for screen-film mammography. Based on figures from the Breast Cancer Detection Demonstration Projects carried out throughout the United States in the 1970s and early 1980s, the average breast doses for two-exposure examinations are 0.08 rads for screen-film technique and 0.74 rads for xeroradiographic technique. Because film-screen mammography and xeroradiographic mammography are considered to have similar accuracy, there has been increasing consumer interest in film-screen mammography with its lower dose.

The radiation doses and risks should be taken in perspective. Assuming the maximum acceptable dose of 1 rad for a two-view examination, the theoretical risk of a radiation-induced breast carcinoma is 3.5 cancers per million women per year per rad. In contrast, the natural incidence of breast carcinoma ranges from 800 cases per million women per year at age 40 to 2,500 cases per million women per year at age 65. The theoretical risks of mammography are comparable to those of everyday activities such as driving a car.

Mammography is an extremely accurate and safe method for evaluating the breasts of symptomatic women older than 30 and asymptomatic women older than 35. The benefit-risk ratio of mammography is highly favorable and, it is hoped,

will continue to improve as additional technologic innovations result in superior images with lower doses.

Noninvasive Doppler Ultrasonography of Carotid Arteries

THE DEVELOPMENT of Doppler ultrasound has greatly enhanced our ability to diagnose a variety of arterial and venous diseases. To date, one of the primary indications for the use of Doppler ultrasound is in investigating cases of possible extracranial carotid artery occlusive disease. This is often referred to as carotid duplex scanning, which is a combination of high-resolution real-time imaging of the carotid arteries with pulsed Doppler wave form and spectral analysis.

In general, patients with a clear-cut history of transient ischemic attacks or reversible ischemic neurologic deficits are studied primarily with selective carotid angiography. Carotid duplex scanning is generally reserved for screening patients who have either an asymptomatic carotid bruit or an unclear history of a transient ischemic attack. In direct comparison studies with selective angiography, carotid duplex scanning has proved to be a reliable technique in showing significant atherosclerotic stenoses at the carotid bifurcation, with accuracies ranging from approximately 85% to 95%. In fact, some authors claim an increased sensitivity for carotid duplex scanning by its ability to detect relatively small plaques that may go undetected by a study such as angiography, which merely shows intraluminal anatomy rather than direct mural lesions.

Specific Doppler criteria for estimating the extent of stenosis have been established by several authors using either a ratio of maximal peak systolic internal carotid flow velocity to maximal common carotid peak systolic flow velocity or using the overall quantitative peak frequency shift obtained within the internal carotid. In persons with normal anatomy, there are both characteristic sounds and wave forms of the internal carotid, external carotid and common carotid arteries. One of the great advantages of carotid duplex scanning is that it combines both anatomic information by virtue of high-resolution real time with the ability to diagnose physiologic disturbances and blood flow with pulsed wave form Doppler analysis. Approximately 10% of carotid bifurcations cannot be adequately imaged with carotid duplex scanning because of a high cervical location of the bifurcation.

One of the major limitations of carotid duplex scanning is that it is operator-dependent. It requires significant experience and commitment to mastering this technique to achieve good results. In experienced hands, however, it is a relatively rapid, noninvasive and inexpensive method of evaluating the carotid bifurcation for significant atheromatous stenoses. To date, the sensitivity for carotid duplex scanning in diagnosing ulcerations is not known, however, because of the inherent tomographic nature of this technique; partial voluming of an irregularly surfaced plaque may lead to misdiagnosis. Because of the ability of carotid duplex scanning to directly image a plaque, in some instances it is possible to characterize the histologic features of a plaque by its sonographic appearance. Calcified plaques produce areas of high-amplitude echoes with acoustic shadowing. Intraplaque hemorrhage has received a great deal of interest in the surgical literature and may be responsible for significant neurologic symptoms, as platelet-aggregate emboli may ensue. Early reports suggest that carotid duplex scanning may have a role in the diagnosis of intraplaque hemorrhage, indicating a biologically unstable plaque even in the absence of a hemodynamically significant stenosis.

When compared with other less invasive techniques such as intravenous digital subtraction angiography, carotid duplex scanning has a number of distinct advantages. First, it is not dependent on patient motion or cardiac output. Second, it is completely noninvasive and does not involve intravenous administration of any contrast media. Third, it is significantly less expensive and often less time consuming. In summary, carotid duplex scanning has proved to be a reliable and clinically useful technique in experienced hands in evaluating significant carotid bifurcation disease.

Magnetic Resonance Imaging

EXPERIENCE WITH the use of magnetic resonance (MR) imaging for clinical diagnosis has been ongoing for more than three years at several centers in the United States and in Great Britain. It is now clear that MR imaging will assume an important place in clinical diagnosis and biomedical research. It has the following distinct advantages: soft tissue contrast resolution far exceeding the limits of computed tomography (CT) and ultrasonography, absence of possible mutagenic effects inherent with ionizing radiation, unequivocal blood pool identification without the need for contrast media and direct imaging in multiple planes (coronal, sagittal, transverse).

These diagnostic advantages have already been recognized for imaging of four parts of the body. MR imaging is the procedure of choice for most purposes in evaluating the central nervous system (CNS), including the spinal cord. Among its advantages are definitively diagnosing leukoencephalopathies such as multiple sclerosis, greater sensitivity for defining brain lesions compared with using CT, improved depiction of lesions in the posterior fossa through sagittal images and freedom from bony artifacts and visualizing the spinal cord without contrast media and discriminating various pathologies within the cord itself.

The natural contrast between the blood pool and cardiovascular structures makes it valuable for cardiovascular imaging. Recent studies have shown its accuracy for the completely noninvasive evaluation of aortic aneurysms and dissections; tumor and bland thrombi within cardiac cham-

bers, arteries and veins; intracardiac and paracardiac masses; presence, site and complications of myocardial infarctions; constrictive pericarditis; hypertrophic cardiomyopathies, and congenital heart disease. Recent reports have indicated its capability for directly visualizing acutely infarcted myocardium and differentiating infarcted from normal myocardial tissue.

High-contrast resolution and multiplanar image acquisition make MR imaging an important modality for imaging of the pelvis, including the diagnosis and staging of prostate, bladder and gynecologic tumors. The sharp discrimination of endometrial and myometrial layers provides the capability to evaluate focal, small tumors and to assess response to oncotherapy and hormonal interventions. Accuracy for the early diagnosis of renal transplant rejection has been shown.

Musculoskeletal applications are now becoming evident: early identification of avascular necrosis, the medullary extent of bone tumors and lumbosacral disc disease. The recent introduction of thinner tomograms (2.5 mm) extends the uses of MR imaging for evaluating disc disease.

The enormous potential of MR imaging has been clearly evident in the first years of clinical operation. The future role is probably underestimated, however, since MR imaging is being compared with other modalities at a time when it is still an immature and rapidly evolving technology.

How Can Organized Medicine Ever Do All the Things It Ought to Do?

EVERYONE HAS IDEAS about what the medical profession and organized medicine ought to be doing at this perplexing moment in the history of health care in this nation. Some might want to declare victory and say that all of today's health care problems are simply the problems of success of a system that brought better health care to more people than at any other time in history. This is true, but it doesn't solve many of the problems we have today. The clock moves forward, and it is the side effects and complications of this unprecedented medical and social achievement that are becoming evident, and with which both medicine and society must try to learn to cope. It is also becoming clear that many of the things that have to be dealt with are all going on at once. None of them can be ignored for long except at some peril. The intensity of these concurrent urgencies seems to be something new. Our accustomed way of doing things, which is to apply our energies and resources to what seem to be the highest priorities at a given moment, is inadequate to deal effectively with this new problem of so many high priority concerns that all need to be dealt with at the same time.

Almost every physician and just about every medical society knows what these concerns are. Each seems to take the form of a crisis, and each new crisis seems to pile on top of all the others before any of them are really solved. We have a malpractice crisis; we have never-ending legislative crises; problems in financing the cost of patient care and medical education; a host of governmental and third party interventions in health care; ethical problems and adversary relationships developing between hospitals and physicians as a result of the element of competition that has recently been introduced into health care, and more recently what appears to be a lessening public approval of the performance of the medical profession as a whole, although a person's own physician still seems to be held in relatively high esteem. And even these are only some of the more pressing problems facing the medical profession. All in all, it is little wonder that physicians are turning to their medical associations for guidance—and solutions. The physician membership in organized medicine may ask if the medical profession can ever hope to deal effectively with all these concurrent problems. Will it ever be possible to do all the things the profession ought to do? It just may be that frustration about this, as well as the ever increasing cost of membership in medical associations, may contribute to the slippages in membership retention that many associations are beginning to experience.

But need this be so? How might organized medicine begin to deal more effectively with all these concurrent and complex problems that are the side effects and complications resulting from a superb medical and social achievement? A good start has been made. The medical profession and organized medicine have not panicked, but remain steadfast in the belief that a physician's first responsibility is to his or her patients and to no one else, and to something called quality of care and, of course, to containing costs as much as possible. But something more will be needed than simply reaffirming principle and reacting piecemeal to crisis piled upon crisis. It will require the marshaling of the special knowledge and skills of the profession and bringing them to bear, not only in the patients' interest but also on the quality and cost of care, on the promotion of health and in the public's interest. The real strength—and power—of the medical profession lies in its special knowledge, skills and expertise and how effectively these are applied in all aspects of health care, including its social, economic and political aspects.

Looked upon in this way, the list of things the medical profession "ought to do" seems virtually limitless. Many specifics have been repeatedly suggested in professional periodicals and in the public communications media. For example, it has been said that only the medical profession has the skill and expertise to identify and eliminate worthless treatments, reduce the iactogenic injuries and disease that sometimes accompany modern diagnosis and treatment, or provide the information needed to correct indefensible variations in the cost of caring for the same conditions with the same results in different locations. It has been suggested that physicians aggressively seek to participate, that the profession bring its knowledge, skills and expertise to bear in the decision-making process at every level of health care, and so begin to counteract the trend to place medical decision making in other hands. Some more specific suggestions that have appeared in this journal include the following: develop computerized patient care data bases so as to measure quality as well as cost of care rendered; explore the concept of "generic" medicine and surgery; promote a problem-solving protocol for the broader problems in health care based on the proved problem-solving techniques a physician uses in a difficult or complex case; develop improved physicians' communication skills with patients and the public; organize patients and their relatives and interested persons in a community into pressure groups to support physicians' efforts in behalf of patients and better patient care.

But the basic problem remains. To do the many things it is said that organized medicine "ought to do," a very large number of things will need to be done at the same time. Perhaps a way to do it is to divide the responsibilities among the many associations in such a fashion that each would be able to contribute a part to the whole of what it is agreed "ought to be done," each in accordance with its own interests, commitment and resources. There are 50 state medical associations and probably hundreds of more-or-less sophisticated county medical societies that could participate, not to mention the specialty societies. If there were some kind of a

master framework to coordinate study and action throughout the profession, then an organizational instrument might be created that could in fact bring the special knowledge and expertise of the medical profession effectively to bear, simultaneously, on so many of the things organized medicine ought to be doing with so many of the presently unstudied and unsolved problems in health care.

MSMW

Screening for Disabilities

ELSEWHERE IN THIS ISSUE Foster and colleagues have provided an excellent description of the activities that physicians should use in their efforts to prevent disabilities or to identify existing disabilities as early as possible. We know why such efforts are important from a medical standpoint. When we cannot actually prevent disabilities, time is of the essence in our efforts to contain and compensate for the effects of a given disability and to hold unnecessary involvement to a minimum.

Where we often fail in medicine, I believe, is in considering the total impact of a disability on the life functioning of our patients. Because our perspective is too physiological, we sometimes miss opportunities to have our medical interventions contribute to improved functioning for the individual person in the world at large. If our choice of medical intervention could be based not only on consideration for the medical condition but also on consideration for keeping a child in school or maintaining a young adult in a vocational program, our patients' well-being would be better served.

Disabilities can affect all aspects of a person's life—educational, employment and social—not just those bracketed off as "health" concerns. Serving patients with disabilities calls for a broad awareness of the nature of disabling conditions in this country and of the service system that is involved with persons with disabilities. For a physician working with disabled patients, this awareness requires the following:

- A knowledge of the facts about disabling conditions. What are the nature and size of the population of persons with disabilities? When are these conditions most likely to occur? How can we be alert to vulnerable periods?
- A knowledge of the resources available for persons with disabilities, locally and in federal and state programs, so that working relationships can be established with the professionals who are or should be involved with a patient at the same time the physician addresses medical needs.

The Population

From 1% to 2% of all newborns have discernible disabilities or developmental defects. This includes visibly obvious structural anomalies such as spina bifida, congenital heart defects that require more subtle examination techniques for detection and problems discovered via biochemical analysis, such as phenylketonuria. Also included are infants having intracranial hemorrhages, respiratory problems requiring ventilation or severe infections occurring during the neonatal period.

Approximately 10% of all children enrolled in this nation's schools are eligible for special education or "related services" under Public Law 94-142, the Education of All Handicapped Children Act of 1975. This includes those with disabling conditions and other developmental problems that interfere with the *education* of a child, including such conditions as relatively mild, transient speech-articulation defects. We seem to be doing well at identifying sensory, cognitive, intellectual or learning problems that directly affect the educational needs of a child, but sometimes children with physiologic disease, motor disorders or emotional problems are less well identified by the education system because the problem does not directly affect the child's educational process.

Approximately 15% of the adults between 18 and 65 years of age in this country are considered disabled to the extent that they do not participate in regular employment. This includes persons affected by severe disabling conditions such as quadriplegia or mental retardation, chronic lower back disabilities, mental illness and those who are malingering.

Approximately 1% of the persons in this country, including some members of the previously described populations, have sensory, cognitive, motor, physiologic or mental health disorders that were manifest before age 22 years and that significantly affect their functional lives. They are known as persons with *developmental disabilities* according to Public Law 98-527, the Developmental Disabilities Act of 1984.

The percentage of persons with developmental disabilities remains fairly constant, both relatively and absolutely. Advances in medical and surgical treatments (such as cardiac surgery) permit a limited number of disabled persons to achieve fully functional lives. Some achieve independence through bioscientific achievements, such as out-of-hospital ventilatory assistance, and others through evolving positive societal attitudes, such as employment opportunities for those with significant retardation. It appears that accidents, degenerative diseases that do not manifest until the teenage years and complications of disease such as arthritis, diabetes and other medical conditions are the principal reasons for additions to the disabled population that cause the rate to remain essentially at 1% of the nation's population over time.

Genetic defects, including chromosomal aberrations, and prenatal environmental causes constitute a large percentage of developmental problems. The majority of prenatal causes remains unknown. At the present time, prenatal identification of such genetic and environmental causes exists for a meaningful but yet small percentage of those who will eventually manifest developmental disabilities. Perinatal causes, especially hypoxia, anoxia and infections, account for a large proportion of all developmental disorders.

An important segment of the developmentally disabled population is made up of children known to have renal disease, cardiomyopathies, muscular disorders, mental illness and other disorders that worsen over time and eventually significantly affect physical and cognitive functions. Knowledgeable physicians and other health professionals initiate screening procedures in their practices to identify their patients who show such signs and symptoms and coordinate or provide the required evaluation and referral services.

Physicians who care for adolescents and young adults often treat the residuals of vehicular accidents, attempted homicides, industrial and construction accidents, diving and other sports-related injuries typical of the fast-paced, action-oriented lives of this segment of our population. This patient cohort's need is not screening for identification, but periodic monitoring to ensure that needed services are available and that the young person is known to all the required educational,

health, vocational and independent-living agencies that can provide appropriate services. Additionally, repetitive depressive episodes, near suicides with mental or physical residuals and eating disorders all have the potential to significantly and permanently affect a young person's life before age 22 years and to qualify that person for services for developmental disability.

Resources

Less than half of the US childhood population regularly visits physicians for child health supervision activities after 36 months of age. This mandates a cooperative process between a child's physician, who has cumulative health and developmental information, and personnel from the child's school who screen and evaluate preschool and school-aged children under PL 94-142 regulations.

In addition, there remains a need for additional physician-initiated clinical activities to effectively screen older children, adolescent and young adult populations to ensure that all persons with developmental disabilities are not only identified but also adequately evaluated and provided with needed services.

But beyond the screening efforts, we need also to make efforts to integrate our medical services with community, state and federal programs that can contribute to the quality of life for patients with disabilities. We should not only be treating the medical problems of a child with spina bifida in our offices, but should also be working closely with school personnel to see that our recommendations for bladder management fit optimally with the child's normal activities and that the school personnel can carry out such recommendations. Does the adolescent we have seen after a suicide attempt have contact with community mental health and family support services, and how can we contribute to the ongoing efforts of those services? How can we steer a high school student with a degenerative neuromuscular disorder toward the vocational services that could help that patient toward a possible career?

This broad approach has not traditionally been within the scope of most clinical practices. In the case of disabling conditions, the awareness of nonmedical needs and resources to meet them is vital to a patient's well-being. For physicians, such integrative efforts offer a way to make the often great challenges of patients with chronic disabilities a shared and more rewarding responsibility.

Ancient Sources of Lead and Lead Poisoning in the United States Today

LEAD IS ONE of the ancient metals. A lead statue in the British Museum discovered in Turkey dates from 6500 BC.[1] Lead has been mined, smelted and used in cosmetics, internal and topical medicinal preparations, paint pigments and glazes throughout the Old World since earliest recorded history.[2] Elsewhere in this issue, two recent cases of lead poisoning in children are presented—one due to azarcon, a Hispanic folk remedy containing lead tetroxide, and the other due to the close proximity of the child's home to a secondary lead smelter. The physicians handling these cases are to be congratulated. Owing to the nonspecificity of the classic clinical manifestations of plumbism, its diagnosis has baffled physicians from antiquity[2] to recent times. Two recent baffling cases were traced to ancient uses of lead, namely, a lead-glazed ceramic mug[3] and a lead-contaminated health food calcium dietary supplement.[4] The definitive laboratory test for the diagnosis of lead poisoning is a whole blood lead test, which has become widely available only in the past decade. Within the past few months, the National Bureau of Standards has made available a certified standard reference material for blood lead analysis (SRM 955, available from the United States Department of Commerce, National Bureau of Standards, Washington, DC 20234) that should further improve the quality of blood lead data.

Lead-bearing ores often contain silver. Following the discovery about 4000 BC of cupellation, a simple process by which silver can be recovered from lead ores, lead was extensively mined throughout the Old World, mainly for its silver content. Nriagu[2] estimates that more than 40 million tons of lead had been produced by the time of the fall of Rome. Although the fact is not recorded, it is not unlikely that children near ancient lead mines and smelters were poisoned in a manner similar to that reported by Sawyer and colleagues. In this most recent case the physicians, having made the diagnosis, are to be congratulated in particular for having taken the next important step, namely, visiting the child's home to collect environmental samples to identify the child's source(s) of lead. It is this step, together with the reporting of index cases to public health authorities,[5] that is essential to trigger an epidemiologic investigation, which in this case apparently led to closure of the smelter and evacuation of the heavily contaminated adjacent area. Similarly, an alert pediatrician trained in an eastern city where childhood plumbism is endemic recognized clinical plumbism in two children from Kellogg, Idaho, where he had gone to practice. He reported these cases which, in turn, resulted in the discovery of an epidemic of subclinical plumbism due to emissions from a large primary lead smelter in Kellogg.[6]

In addition to children who live near lead smelters, children (and other housemates) of lead workers who bring lead-bearing dust home on their work clothing are also at risk. Several clusters of such cases, particularly in relation to lead and asbestos, have been identified.[7] These cases illustrate the need for physicians to take both environmental and occupational histories. All family members of index cases should be considered regardless of age, and cases should be reported so that appropriate epidemiologic investigations and public health action can be undertaken.

Ceruse (lead carbonate), litharge (lead monoxide) and other oxides of lead and galena (lead sulfide) have been used in the Old World throughout recorded history as cosmetics and basic ingredients in medicaments, nostrums and folk remedies.[2] Lead sulfide is still used today as a black eye cosmetic and is known on the Indian subcontinent as *surma* and in the Arabic world as *kohl*. Recently, severe cases of plumbism in children from both cosmetic[8] and medicinal uses[9] of lead sulfide have been reported. The Greco-Romans used lead carbonate and the oxides of lead primarily in topical medica-

tions and only to a limited extent in internal remedies. The ancient Chinese, however, used lead to a much greater extent in herbal medicines given internally.[2] Furthermore, these concoctions may contain arsenic, mercury or both.

Not surprisingly, some people who come to the United States from Asia, the Middle East and South America bring with them these ancient folk remedies, although they may be reluctant to admit it. For example, the Centers for Disease Control (CDC) have recently reported cases of both lead and arsenic poisoning among Hmong refugees in the United States due to or suspected of being due to imported folk remedies.[10,11] Hmong people residing in the United States are concentrated mainly in San Diego, Fresno and Stockton, California, and Minneapolis.[10] Cases of plumbism due to both Indian[12] and Chinese[13] folk remedies have been identified in the West within the past decade. Preparations containing lead, arsenic or mercury are used in folk medicine, not only as remedies for such complaints as *empacho,* fever and rash, but also as tonics and salves.

While one of the cases reported elsewhere in this issue was due to lead tetroxide (azarcon, also known as *greta*), recent surveillance by the CDC makes it clear that we must extend our horizons beyond Mexico to include immigrants from all parts of Asia. Our horizons must also be extended by the realization that arsenic and mercury may also be present in such folk remedies. It is only 40 years since arsenicals were replaced by penicillin in the treatment of syphilis in the western world. Perhsgen's observation that arsenicals could be found in Belgium in over-the-counter medications as late as 1978 should make the traveler wary.[14] These events present a considerable challenge to physicians and allied health professionals working in concert with leaders of ethnic groups newly arrived in the US, if deeply engrained ancient but dangerous cultural practices are to be changed.

Tetraethyl lead was discovered in the United States by Thomas Midgely in 1921, added to gasoline in 1923 and raised a public health controversy from the very beginning.[15] After the intense public scrutiny of the past 15 years, it appears that this most recent source of widespread low-level environmental contamination by lead will shortly end. The US Environmental Protection Agency has ruled that the lead content of gasoline be reduced to 0.1 grams per gallon by 1 January 1986 and has proposed a complete ban as early as 1988.[16] This is likely to leave lead paint, another ancient use of lead, as the major lead-related public health problem in the United States, particularly in the older housing in the East and the Midwest.[17] Not only are poor children in deteriorated old housing still at risk, but so also are urban homesteaders who renovate old housing.[18] Although it is well known that virtually all housing built in the United States before 1940 contained lead pigment paints, it may not be appreciated that approximately 20% of housing built between 1960 and 1975 contains potentially hazardous amounts of lead on exposed interior surfaces.[19] The distribution of paint containing lead additives (driers and pigments) intended for exposed interior and exterior residential surfaces was finally banned in interstate commerce by the Consumer Products Safety Commission in September 1977.[20] Decades may pass before lead-painted housing is either replaced or totally renovated. Thus, the ancient causes of serious and even fatal lead poisoning—paint, folk remedies and tonics, cosmetics and dangerous lead trades such as lead smelting—remain with us, while one of the most recent discoveries—tetraethyl and tetramethyl lead—departs the scene after a brief stay of about 70 years. Lead is a versatile metal with many uses. This makes it incumbent upon physicians to consider the many possible sources of exposure for a given child[21] and to initiate the environmental investigation necessary to identify the source(s). Reducing or eliminating the source is the cornerstone of therapy for lead poisoning. Primary prevention is, of course, the long-term goal.
